IDENTIFICATION AND ESTIMATION OF AVERAGE PARTIAL EFFECTS IN “IRREGULAR” CORRELATED RANDOM COEFFICIENT PANEL DATA MODELS

BY BRYAN S. GRAHAM AND JAMES L. POWELL

In this paper we study identification and estimation of a correlated random coefficients (CRC) panel data model. The outcome of interest varies linearly with a vector of endogenous regressors. The coefficients on these regressors are heterogeneous across units and may covary with them. We consider the average partial effect (APE) of a small change in the regressor vector on the outcome (cf. Chamberlain (1984), Wooldridge (2005a)). Chamberlain (1992) calculated the semiparametric efficiency bound for the APE in our model and proposed a \( \sqrt{N} \)-consistent estimator. Nonsingularity of the APE’s information bound, and hence the appropriateness of Chamberlain’s (1992) estimator, requires (i) the time dimension of the panel (\( T \)) to strictly exceed the number of random coefficients (\( p \)) and (ii) strong conditions on the time series properties of the regressor vector. We demonstrate irregular identification of the APE when \( T = p \) and for more persistent regressor processes. Our approach exploits the different identifying content of the subpopulations of stayers—or units whose regressor values change little across periods—and movers—or units whose regressor values change substantially across periods. We propose a feasible estimator based on our identification result and characterize its large sample properties. While irregularity precludes our estimator from attaining parametric rates of convergence, its limiting distribution is normal and inference is straightforward to conduct. Standard software may be used to compute point estimates and standard errors. We use our methods to estimate the average elasticity of calorie consumption with respect to total outlay for a sample of poor Nicaraguan households.

KEYWORDS: Panel data, correlated random coefficients, semiparametric efficiency, irregularity, calorie demand.

THAT THE AVAILABILITY of multiple observations of the same sampling unit (e.g., individual, firm, etc.) over time can help to control for the presence of unobserved heterogeneity is both intuitive and plausible. The inclusion of unit-specific intercepts in linear regression models is among the most widespread methods of “controlling for” omitted variables in empirical work (e.g., Card

The appropriateness of this modelling strategy, however, hinges on any time-invariant correlated heterogeneity entering the outcome equation additively. Unfortunately, additivity, while statistically convenient, is difficult to motivate economically (cf. Imbens (2007)).\(^2\) Browning and Carro (2007) presented a number of empirical panel data examples where nonadditive forms of unobserved heterogeneity appear to be empirically relevant.

In this paper, we study the use of panel data for identifying and estimating what is arguably the simplest statistical model admitting nonseparable heterogeneity: the correlated random coefficients (CRC) model. Let \(Y = (Y_1, \ldots, Y_T)\)' be a \(T \times 1\) vector of outcomes and let \(X = (X_1, \ldots, X_T)'\) be a \(T \times p\) matrix of regressors with \(X_t \in X_t \subset \mathbb{R}^p\) and \(X \in X_T\), where \(X_T = \times_{t \in \{1, \ldots, T\}} X_t\). We assume that \(X_t\) is strictly exogenous. This rules out feedback from the period \(t\) outcome \(Y_t\) to the period \(s \geq t\) regressor \(X_s\). One implication of this assumption is that lags of the dependent variable may not be included in \(X_t\). Our model is static.

Available is a random sample \(\{(Y_i, X_i)\}_{i=1}^N\) from a distribution \(F_0\). The \(t\)th period outcome is given by

\[
Y_t = X_t b_t(A, U_t) \tag{1}
\]

where \(A\) is time-invariant unobserved unit-level heterogeneity and \(U_t\) is a time-varying disturbance. Both \(A\) and \(U_t\) may be vector-valued. The \(p \times 1\) vector of functions \(b_t(A, U_t)\), which we allow to vary over time, map \(A\) and \(U_t\) into unit-by-period-specific slope coefficients. By random coefficients, we mean that \(b_t(A, U_t)\) varies across units. By correlated, we mean that the entire path of regressor values, \(X_t\), may have predictive power for \(b_t(A, U_t)\). This implies that an agent’s incremental return to an additional unit of \(X_t\) may vary with \(X_t\). In this sense, \(X_t\) may be endogenous.

Equation (1) is structural in the sense that the unit-specific function

\[
Y_t(x_t) = x_t' b_t(A, U_t) \tag{2}
\]

traces out a unit’s period \(t\) potential outcome across different hypothetical values of \(x_t \in X_t\).\(^3\) Let \(X_t = (1, X_t')'\); setting \(b_{1t}(A, U_t) = \beta_1 + A + U_t\) (with \(A\) and \(U_t\) scalar and mean zero) and \(b_{kt}(A, U_t) = \beta_k\) for \(k = 2, \ldots, p\) yields the textbook linear panel data model

\[
Y_t(x_t) = x_t' \beta + A + U_t \tag{3}
\]

for \(\beta = (\beta_1, \ldots, \beta_p)'\). Equation (2), while preserving linearity in \(X_t\), is more flexible than (3) in that it allows for time-varying random coefficients on all

\(^2\)Chamberlain (1984) presented several well formulated economic models that do imply linear specifications with unit-specific intercepts.

\(^3\)Throughout we use capital letters to denote random variables, lowercase letters to denote specific realizations of them, and bold letters to denote their support (e.g., \(X, x, \) and \(X\)).
AVERAGE PARTIAL EFFECTS IN PANEL DATA MODELS 2107

of the regressors (not just the intercept). Furthermore, these coefficients may nonlinearly depend on \( A \) and/or \( U_t \).

Our goal is to characterize the effect of an exogenous change in \( X_t \) on the probability distribution of \( Y_t \). By exogenous change, we mean an external manipulation of \( X_t \) in the sense described by Blundell and Powell (2003) or Imbens and Newey (2009). We begin by studying identification and estimation of the average partial effect (APE) of \( X_t \) on \( Y_t \) (cf. Chamberlain (1984), Blundell and Powell (2003), Wooldridge (2005a)). Under (1), the average partial effect is given by

\[
\beta_{0t} \equiv \mathbb{E} \left[ \frac{\partial Y_t(X_t)}{\partial X_t} \right] = \mathbb{E} [ b_t(A, U_t) ].
\]

Identification and estimation of (4) is nontrivial because, in our setup, \( X_t \) may vary systematically with \( A \) and/or \( U_t \). To see the consequences of such dependence, observe that the derivative of the mean regression function of \( Y_t \) given \( X_t = x \) does not identify a structural parameter. Differentiating through the integral, we have

\[
\frac{\partial \mathbb{E}[Y_t|X_t = x]}{\partial X_t} = \beta_{0t}(x) + \mathbb{E} \left[ Y_t(X_t)S_{X_t}(A, U_t|X)|X = x \right],
\]

with \( \beta_{0t}(x) = \mathbb{E} [ b_t(A, U_t)|X = x ] \) and \( S_{X_t}(A, U_t|X) = \nabla_{X_t} \log f(A, U_t|X) \). The second term is what Chamberlain (1982) called heterogeneity bias. If the (log) density of the unobserved heterogeneity varies sharply with \( x_t \)—corresponding to “selection bias” or “endogeneity” in a unit’s choice of \( x_t \), then the second term in (5) can be quite large.

Chamberlain (1982) studied identification of \( \beta_{0t} \) \( \equiv \beta_{00} \) using panel data (cf. Mundlak (1961, 1978b)). In a second paper, Chamberlain (1992, pp. 579–585) calculated the semiparametric variance bound for \( \beta_{0t} \) and proposed an efficient method-of-moments estimator.\(^4\) His approach is based on a generalized within-group transformation, naturally extending the idea that panel data allow the researcher to control for time-invariant heterogeneity by “differencing it away.”\(^5\) Under regularity conditions, which ensure nonsingularity of \( \beta_{0t} \)’s information bound, Chamberlain’s estimator converges at the standard \( \sqrt{N} \) rate.

Nonsingularity of \( \mathcal{I}(\beta_{0t}) \), the information for \( \beta_{0t} \), requires the time dimension of the panel to exceed the number of random coefficients (\( T > p \)). Depending on the time series properties of the regressors, \( T \) may need to substantially

\[^4\] Despite its innovative nature, and contemporary relevance given the resurgence of interest in models with heterogenous marginal effects, Chamberlain’s work on the CRC model is not widely known. The CRC specification is not discussed in Chamberlain’s own Handbook of Econometrics chapter (Chamberlain (1984)), while the panel data portion of Chamberlain (1992) is only briefly reviewed in the more recent survey by Arellano and Honoré (2001).

\[^5\] Bonhomme (2010) further generalized this idea, introducing a notion of “functional differencing.”
exceed \(p\). In extreme cases, \(I(\beta_0)\) may be zero for all values of \(T\). In such settings, Chamberlain’s method breaks down. We show that, under mild conditions, \(\beta_0\) nevertheless remains identified. Our method of identification is necessarily “irregular”: the information bound is singular and hence no regular \(\sqrt{N}\)-consistent estimator exists (Chamberlain (1986)). We develop a feasible analog estimator for \(\beta_0\) and characterize its large sample properties. Although its rate of convergence is slower than the standard parametric rate, its limiting distributions is normal. Inference is straightforward.

Our work shares features with other studies of irregularly identified semiparametric models (e.g., Chamberlain (1986), Manski (1987), Heckman (1990), Abrevaya (2000), Honoré and Kyriazidou (2000), Kyriazidou (1997), Andrews and Schafgans (1998), Khan and Tamer (2010)). A general feature of irregular identification is its dependence on the special properties of small subpopulations. These special properties are, in turn, generated by specific features of the semiparametric model. Consequently these types of identification arguments tend to highlight the importance, sometimes uncomfortably so, of maintained modelling assumptions (cf. Chamberlain (1986, pp. 205–207), Khan and Tamer (2010)).

Our approach exploits the different properties, borrowing a terminology introduced by Chamberlain (1982), of “movers” and “stayers.” Loosely speaking these two subpopulations, respectively, correspond to those units whose regressors values, \(X_t\), change and do not change across periods (a precise definition in terms of singularity of a unit-specific design matrix is given below). We identify aggregate time effects using the variation in \(Y_t\) in the stayers subpopulation. A common trends assumption allows us to extrapolate these estimated effects to the entire population. Having identified the aggregate time effects using stayers, we then identify the APE by the limit of a trimmed mean of a particular unit-specific vector of regression coefficients.

**Connection to other work on panel data.** To connect our work to the wider panel data literature, it is useful to consider the more general outcome response function

\[
Y_t(x_t) = m(x_t, A, U_t).
\]

Identification of the APE in the above model can be achieved by one of two main classes of restrictions. The *correlated random effects* approach invokes assumptions on the joint distribution of \((U, A)\) with \(U = (U_1, \ldots, U_T)'\). Mundlak (1978a, 1978b) and Chamberlain (1980, 1984) developed this approach for the case where \(m(X_t, A, U_t)\) and \(F(U, A|X)\) are parametrically specified. Newey (1994a) considered a semiparametric specification for \(F(U, A|X)\) (cf. Arellano and Carrasco (2003)). Recently, Altonji and Matzkin (2005) and Bester and Hansen (2009) extended this idea to the case where \(m(X_t, A, U_t)\) is either semi- or nonparametric along with \(F(U, A|X)\).
The fixed effects approach imposes restrictions on $m(X_t, A, U_t)$ and $F(U|X, A)$, while leaving $F(A|X)$, the distribution of the time-invariant heterogeneity, the so-called fixed effects, unrestricted. Works by Chamberlain (1980, 1984, 1992), Manski (1987), Honoré (1992), Abrevaya (2000), and Bonhomme (2010) are examples of this approach. Depending on the form of $m(X_t, A, U_t)$, the fixed effect approach may not allow for a complete characterization of the effect of exogenous changes in $X_t$ on the probability distribution of $Y_t$. Instead only certain features of this relationship can be identified (e.g., ratios of the average partial effect of two regressors).

Our methods are of the “fixed effect” variety. In addition to assuming the CRC structure for $Y_t(x_t)$, we impose a marginal stationarity restriction on $F(U_t|X, A)$, a restriction also used by Manski (1987), Honoré (1992), and Abrevaya (2000); however, other than some weak smoothness conditions, we leave $F(A|X)$ unrestricted.

Wooldridge (2005b) and Arellano and Bonhomme (2012) also analyzed the CRC panel data model. Wooldridge focused on providing conditions under which the usual linear fixed effects (FE) estimator is consistent despite the presence of correlated random coefficients (cf. Chamberlain (1982, p. 11)). Arellano and Bonhomme (2012) studied the identification and estimation of higher-order moments of the distribution of the random coefficients. Unlike us, they maintained Chamberlain’s (1992) regularity conditions as well as imposed additional assumptions.

Chamberlain (1982, p. 13) showed that when $X_t$ is discretely valued, the APE is generally not identified. However, Chernozhukov, Fernández-Val, Hahn, and Newey (2009), working with more general forms for $E[Y_t|X, A]$, showed that when $Y_t$ has bounded support, the APE is partially identified, and proposed a method of estimating the identified set. In contrast, in our setup we show that the APE is point identified when at least one component of $X_t$ is continuously valued.

Section 1 presents our identification results. We begin by (i) briefly reviewing the approach of Chamberlain (1992) and (ii) characterizing irregularity in the CRC model. We then present our method of irregular identification. Section 2 outlines our estimator as well as its large sample properties. Section 3 discusses various extensions of our basic approach.

In Section 4, we use our methods to estimate the average elasticity of calorie demand with respect to total household resources in a set of poor rural communities in Nicaragua. Our sample is drawn from a population that participated in a pilot of the conditional cash transfer program Red de Protección Social (RPS). Hunger, conventionally measured, is widespread in the communities from which our sample is drawn; we estimate that immediately prior to the

---

6They considered the probit and logit models with unit-specific intercepts (in the index) in detail. They showed how to construct bounds on the APE despite the incidental parameters problem and provided conditions on the distribution of $X_t$ such that these bounds shrink as $T$ grows.
start of the RPS program, over half of households had less than the required number of calories needed for all their members to engage in “light activity” on a daily basis.\(^7\)

A stated goal of the RPS program is to reduce childhood malnutrition, and consequently increase human capital, by directly augmenting household income in exchange for regular school attendance and participation in preventive health care checkups.\(^8\) The efficacy of this approach to reducing childhood malnutrition largely depends on the size of the average elasticity of calories demanded with respect to income across poor households.\(^9\) While most estimates of the elasticity of calorie demand are significantly positive, several recent estimates are small in value and/or imprecisely estimated, casting doubt on the value of income-oriented antihunger programs (Behrman and Deolalikar (1987)).\(^10\)

Disagreement about the size of the elasticity of calorie demand has prompted a vigorous methodological debate in development economics. Much of this debate has centered, appropriately so, on issues of measurement and measurement error (e.g., Bouis and Haddad (1992), Bouis (1994), Subramanian and Deaton (1996)). The implications of household-level correlated heterogeneity in the underlying elasticity for estimating its average, in contrast, have not been examined. If, for example, a households’ food preferences or preferences toward child welfare covary with those governing labor supply, then its elasticity will be correlated with total household resources. An estimation approach that presumes the absence of such heterogeneity will generally be inconsistent for the parameter of interest. Our statistical model and corresponding estimator provide an opportunity, albeit in a specific setting, for assessing the relevance of these types of heterogeneities.

We compare our CRC estimates of the elasticity of calorie demand with those estimated using standard panel data estimators (e.g., Behrman and Deolalikar (1987), Bouis and Haddad (1992)), as well as those derived from cross-sectional regression techniques as in Strauss and Thomas (1990, 1995), Subramanian and Deaton (1996), and others. Our preferred CRC elasticity

---

\(^7\)We use Food and Agricultural Organization (FAO, 2001) gender- and age-specific energy requirements for light activity, as reported in Appendix 8 of Smith and Subandoro (2007), and our estimates of total calories available at the household level to calculate the fraction of households suffering from “food insecurity.”

\(^8\)Worldwide, the Food and Agricultural Organization (FAO) estimates that 854 million people suffered from protein-energy malnutrition in 2001–2003 (FAO (2006)). Halving this number by 2015, in proportion to the world’s total population, is the first United Nations Millennium Development Goal. Chronic malnutrition, particularly in early childhood, may adversely affect cognitive ability and economic productivity in the long run (e.g., Dasgupta (1993)).

\(^9\)Another motivation for studying this elasticity has to do with its role in theoretical models of nutrition-based poverty traps (see Dasgupta (1993) for a survey).

\(^10\)Wolfe and Behrman (1983), using data from Somoza-era Nicaragua, estimated a calorie elasticity of just 0.01. Their estimate, if accurate, suggests that the income supplements provided by the RPS program should have little effect on caloric intake.
estimates are 10–30 percent smaller than their corresponding textbook linear fixed effects ordinary least squares estimates (FE-OLS). Our results are consistent with the presence of modest correlated random coefficients bias.

Section 5 summarizes and suggests areas for further research. Proofs are given in the Appendix. The notation $0_{T \times 1}$, $1_{T \times 1}$, $I_T$, and $D = \sum a_i$, respectively, denotes a $T \times 1$ vector of zeros, a $T \times 1$ vector of ones, the $T \times T$ identity matrix, and equality in distribution.

1. IDENTIFICATION

Our benchmark data generating process combines (1) with the following assumption.

ASSUMPTION 1.1—Stationarity and Common Trends:

(i) $b_t(A, U_t) = b^*(A, U_t) + d_t(U_{2t})$ for $t = 1, \ldots, T$ and $U_t = (U_{1t}, U_{2t})'$.

(ii) $U_t | X, A \overset{D}{=} U_s | X, A$ for $t = 1, \ldots, T, t \neq s$.

(iii) $U_{2t} | X, A \overset{D}{=} U_{2s}$ for $t = 1, \ldots, T$.

(iv) $E[b_t(A, U_t)|X = x]$ exists for all $t = 1, \ldots, T$ and $x \in X^T$.

Part (i) of Assumption 1.1 implies that the random coefficient consists of a “stationary” and a “nonstationary” component. The stationary part, $b^*(A, U_t)$, does not vary over time, so that if $U_t = U_s$, we have $b^*(A, U_t) = b^*(A, U_s)$. The nonstationary part, which is a function of the subvector $U_{2t}$ alone, may vary over time, so that even if $U_{2t} = U_{2s}$, we may have $d_t(U_{2t}) \neq d_s(U_{2s})$.

Part (ii) imposes marginal stationarity of $U_t$ given $X$ and $A$ (cf. Manski (1987)). Stationarity implies that the joint distribution of $(U_t, A)$ given $X$ does not depend on $t$. This implies that time may not be used to forecast values of the unobserved heterogeneity. While (ii) allows for serial dependence in $U_t$, it rules out time-varying heteroscedasticity. Part (iii) requires that $U_{2t}$ is independent of both $X$ and $A$. Maintaining (ii) and (iii) is weaker than assuming that $U_t$ is independent and identically distributed (i.i.d.) over time and independent of $X$ and $A$ as is often done in nonlinear panel data research (e.g., Chamberlain (1980)). Part (iv) is a technical condition. Note that Assumption 1.1 does not restrict the joint distribution of $X$ and $A$. Our model is a “fixed effects” model.

Under Assumption 1.1, we have

\begin{align*}
\mathbb{E}[b_t(A, U_t)|X] &= \mathbb{E}[b^*(A, U_t)|X] + \mathbb{E}[d_t(U_{2t})|X] \\
&= \mathbb{E}[b^*(A, U_t)|X] + \mathbb{E}[d_t(U_{2t})] \\
&= \beta_0(X) + \delta_{0t}, \quad t = 1, \ldots, T,
\end{align*}

where the first equality uses part (i) of Assumption 1.1, the second equality uses parts (ii) and (iii), and the third equality establishes the notations $\beta_0(X) = \mathbb{E}[b^*(A, U_t)|X]$ and $\delta_{0t} = \mathbb{E}[d_t(U_{2t})]$. In what follows, we normalize $\delta_{01} = 0$. 
Equation (6) is a “common trends” assumption. To see this, consider two subpopulations with different regressor histories \( \mathbf{X} = \mathbf{x} \) and \( \mathbf{X} = \mathbf{x}' \). Restriction (6) implies that

\[
E\left[ b_i(A, U_i) | \mathbf{x} \right] - E\left[ b_i(A, U_i) | \mathbf{x} \right] = E\left[ b_i(A, U_i) | \mathbf{x} \right] - E\left[ b_i(A, U_i) | \mathbf{x} \right] = \delta_{0r} - \delta_{0s}.
\]

Now recall that a unit’s period \( t \) potential outcome function is \( Y_t(\mathbf{x}_t) = \mathbf{x}'_t b_t(A, U_t) \). Letting \( \tau \) be any point in the support of both \( \mathbf{X}_t \) and \( \mathbf{X}_s \), we have for all \( \mathbf{x} \in \mathbb{X}^T \),

\[
E\left[ Y_t(\tau) - Y_s(\tau) | \mathbf{X} = \mathbf{x} \right] = E\left[ Y_t(\tau) - Y_s(\tau) | \mathbf{X} = \mathbf{x} \right] = \tau' (\delta_{0r} - \delta_{0s}).
\]

Equation (7) implies that while the period \( t \) (linear) potential outcome functions may vary arbitrarily across subpopulations defined in terms of \( \mathbf{X} = \mathbf{x} \), shifts in these functions over time are mean independent of \( \mathbf{X} \). A variant of (7) is widely employed in the program evaluation literature (e.g., Heckman, Ichimura, Smith, and Todd (1998), Angrist and Krueger (1999)). It is also satisfied by the linear panel data model featured in Chamberlain (1984).\(^{11}\)

Let the \((T - 1)p \times 1\) vector of aggregate shifts in the random coefficients \((\delta'_2, \ldots, \delta'_T)'\) be denoted by \( \mathbf{\delta} \) with the corresponding \( T \times (T - 1)p \) matrix of time shifters given by

\[
W = \begin{pmatrix}
0_p' & 0_p' \\
0_p' & 0_p' \\
\mathbf{X}_2' & 0_p' \\
\vdots & \ddots \\
0_p' & 0_p' \\
0_p' & \mathbf{X}_T'
\end{pmatrix}.
\]

Under Assumption 1.1, we can write the conditional expectation of \( \mathbf{Y} \) given \( \mathbf{X} \) as

\[
E[\mathbf{Y} | \mathbf{X}] = W\mathbf{\delta}_0 + \mathbf{X}\mathbf{\beta}_0(\mathbf{X}).
\]

In some cases, it will be convenient to impose a priori zero restrictions on \( \mathbf{\delta}_0 \) (which would imply restrictions on how \( E[Y_t(\mathbf{x}_t)] \) is allowed to vary over time). To accommodate such situations (without introducing additional notation), we can simply redefine \( W \) and \( \mathbf{\delta}_0 \) accordingly. For example, a model that allows only the intercept of \( E[Y_t(\mathbf{x}_t)] \) to shift over time is given by (9) above with

\(^{11}\)In a National Bureau of Economic Research (NBER) working paper, we showed how to weaken (6) while still getting positive identification results. As we do not use these additional results when considering estimation, they are omitted. Formulating a specification test based on the overidentifying implications of (6) would be straightforward.
\( W = (0_{T-1}, I_{T-1})' \) and \( \delta_0 \) equal to the \( T - 1 \) vector of intercept shifts. To accommodate a range of options, we henceforth assume that \( W \) is a \( T \times q \) function of \( X \).

Equation (9), which specifies a semiparametric mean regression function for \( Y \) given \( X \), is the fundamental building block of the results that follow. Our identification results are based solely on different implications of (9). The role of equation (1) and Assumption 1.1 is to provide primitive restrictions on \( F_0 \) that imply (9). We emphasize that our results neither hinge on nor necessarily fully exploit all of these assumptions. Rather, they flow from just one of their implications.

1.1. Regular Identification

The partially linear form of (9) suggests identifying \( \delta_0 \) using the conditional variation in \( W \) given \( X \) as in, for example, Engle, Granger, Rice, and Weiss (1986). In our benchmark model, however, \( W \) is a \( T \times q \) function of \( X \) and hence no such conditional variation is available. Nevertheless, Chamberlain (1992) has shown that \( \delta_0 \) can be identified using the panel structure.

Let \( \Phi(X) \) be some function of \( X \) mapping into \( T \times T \) positive definite matrices (in practice, \( \Phi(X) = I_T \) will often suffice) and define the \( T \times T \) idempotent “residual maker” matrix

\[
M_\Phi(X) = I_T - X[X'\Phi^{-1}(X)X]^{-1}X'\Phi^{-1}(X).
\]

Using the fact that \( M_\Phi(X)X = 0 \), Chamberlain (1992) derived, for \( T > p \), the pair of moment restrictions

\[
\mathbb{E} \left[ \begin{array}{c}
W'\Phi^{-1}(X)M_\Phi(X)(Y - W\delta_0) \\
X'\Phi^{-1}(X)^{-1}X'\Phi^{-1}(X)(Y - W\delta_0) - \beta_0
\end{array} \right] = 0,
\]

which identify \( \delta_0 \) and \( \beta_0 \) by

\[
\delta_0 = \mathbb{E}[\bar{W}_\Phi \Phi^{-1}(X)\bar{W}_\Phi]^{-1} \times \mathbb{E}[\bar{W}_\Phi \Phi^{-1}(X)\bar{Y}_\Phi],
\]

\[
\beta_0 = \mathbb{E}[(X'\Phi^{-1}(X))^{-1}X'\Phi^{-1}(X)(Y - W\delta_0)],
\]

where \( \bar{W}_\Phi = M_\Phi(X)W \) and \( \bar{Y}_\Phi = M_\Phi(X)Y \).

Note that \( M_\Phi(X) \) can be viewed as a generalization of the within-group transform. To see this, note that premultiplying (9) by \( M_\Phi(X) \) yields

\[
\mathbb{E}[\bar{Y}_\Phi|X] = \bar{W}_\Phi \delta_0 + M_\Phi(X)X\beta_0(X) = \bar{W}_\Phi \delta_0,
\]

\(^{12}\)To be specific, if \( \bar{W} = W - \mathbb{E}[W|X] \) has a covariance matrix of full rank, then \( \delta_0 = \mathbb{E}[\bar{W}\bar{W}]^{-1} \times \mathbb{E}[\bar{W}Y] \).
so that $M_\theta(X)$ “differences away” the unobserved correlated effects, $\beta_0(X)$. Equation (11) shows that $\delta_0$ is identified by the remaining within-group variation in $W_i$.

With $\delta_0$ asymptotically known, the APE is then identified by the (population) mean of the unit-specific generalized least squares (GLS) fits

$$\hat{\beta}_i = (X_i'\Phi^{-1}(X_i)X_i)^{-1}X_i'\Phi^{-1}(X_i)(Y_i - W_i\delta_0).$$

Chamberlain (1992) showed that setting $\Phi(X) = \Sigma(X) = \text{V}(Y|X)$ is optimal, resulting in estimators with asymptotic sampling variances equal to the variance bounds

$$\mathcal{I}(\delta_0)^{-1} = \mathbb{E}\left[W_2^T\Sigma^{-1}(X)W_2\right]^{-1},$$

$$\mathcal{I}(\beta_0)^{-1} = \mathbb{V}(\beta_0(X)) + \mathbb{E}\left[(X'\Sigma^{-1}(X)X)^{-1}\right] + K\mathcal{I}(\delta_0)^{-1}K',$$

where $K = \mathbb{E}[X'\Sigma^{-1}(X)X]^{-1}X'\Sigma^{-1}(X)W]$. 

1.2. Irregularity of the CRC Panel Data Model

Chamberlain’s approach requires nonsingularity of $\mathcal{I}(\delta_0)$ and $\mathcal{I}(\beta_0)$. In this section, we discuss when this condition does not hold and, consequently, no regular $\sqrt{N}$-consistent estimator exists. We begin by noting that singularity $\mathcal{I}(\delta_0)$ and $\mathcal{I}(\beta_0)$ is generic if $T = p$. The following proposition specializes Proposition 1 of Chamberlain (1992) to our problem.

**Proposition 1.1—Zero Information:** Suppose that (i) $(F_0, \delta_0, \beta_0(\cdot))$ satisfies (9), (ii) $\Sigma(x)$ is positive definite for all $x \in X^T$, (iii) $\mathbb{E}[W \Sigma^{-1}(X)W] < \infty$, and (iv) $T = p$. Then $\mathcal{I}(\delta_0) = 0$.

**Proof:** From Chamberlain (1992), the information bound for $\delta_0$ is given by

$$\mathcal{I}(\delta_0) = \mathbb{E}\left[\tilde{W}_2^T\Sigma^{-1}(X)\tilde{W}_2\right]$$

so that $\alpha'\mathcal{I}(\delta_0)\alpha = 0$ is equivalent to $\tilde{W}_2\alpha = 0$ with probability 1. If $T = p$, then $X$ is square so that

$$\tilde{W}_2 = W(I_T - X[X'\Sigma^{-1}(X)X]^{-1}X'\Sigma^{-1}(X)) = 0$$

such that $\tilde{W}_2\alpha = 0$. 

An intuition for Proposition 1.1 is that when $T = p$ Chamberlain’s generalized within-group transform of $W$ eliminates all residual variation in $W_i$ over
time. This is because the \( p \) predictors \( X_t \) perfectly (linearly) predict each element of \( W_t \) when \( T = p \). Consequently the deviation of \( W_t \) from its within-group mean is identically equal to zero; any approach based on within-unit variation will necessarily fail.

As a simple example, consider the one period \( (T = p = 1) \) panel data model where, suppressing the \( t \) subscript,

\[
Y = \delta_0 + X b(A, U),
\]

with \( X \) scalar. Under Assumption 1.1, this gives (9) with \( W = 1 \) and \( X = X \). The generalized within-group operator for this model is \( M_{\phi}(X) = 1 - X \left( \frac{X^2}{\phi(X)} \right)^{-1} X \left( \frac{X}{\phi(X)} \right) = 0 \). Consequently, \( Y_I = W_I = 0 \) and (11) does not identify \( \delta_0 \).

By Proposition 1.1, \( I(\delta_0) = 0 \). We show that \( \delta_0 \) and \( \beta_0 \) are irregularly identified in this model below.

We do not provide a general result on when regular \( \sqrt{N} \) estimation of \( \beta_0 \) is possible. However, some insight into this question can be gleaned from a few examples. First, when \( T = p \), it appears as though \( \beta_0 \) will not be regularly identifiable unless \( \delta_0 \) is known. This can be conjectured by the form of (15), which will generally be infinite if \( I(\delta_0)^{-1} \) is. Even if \( \delta_0 \) is known, regular identification can be delicate. Consider the \( T = p = 1 \) model given above. In this model, the right-hand side of (12) above specializes to

\[
E\left[ \frac{Y - \delta_0}{X} \right],
\]

which will be undefined if \( X \) has positive density in the neighborhood of zero.

Less obviously, regular estimation may be impossible in heavily overidentified models (i.e., those where \( T \) substantially exceeds \( p \)). To illustrate, again consider (16) with \( \delta_0 \) known, but with \( T \geq 2 \). Assume further that \( \Sigma(X) = I_T \) and \( X_t = S \cdot Z_t \) where

\[
S \sim \mathcal{U}[a, b], \quad Z_t \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, 1).
\]

Variation in \( X_t \) over time in this model is governed by \( S \), which varies across units. For those units with \( S \) close to zero, \( X_t \) will vary little across periods. The unit-specific design matrix in this model is given by \( X \Sigma^{-1}(X)X = \sum Z_t^2 \cdot S \sim \chi_T^2 \cdot \mathcal{U}[a, b] \). If \( 0 < a < b \), then

\[
\mathbb{E}\left[ (X \Sigma^{-1}(X)X)^{-1} \right] = \begin{cases} \ln(b) - \ln(a) / \frac{T - 2}{T}, & T \geq 3, \\ \infty, & T < 3, \end{cases}
\]

so the right-hand side of (12) will be well defined if \( T \geq 3 \). If \( a \leq 0 \), then it is undefined regardless of the number of time periods. If \( a \leq 0 \), the support of \( S \) will contain zero, ensuring a positive density of units whose values of \( X_t \) do

13 In contrast the variance bound for \( \delta_0 \) will be finite when \( T > p \) as long as there is some variation in \( X_t \) over time.
not change over time. These stayers will have singular design matrices in (13), causing the variance bound for $\beta_0$ to be infinite.

To summarize, regular identification of $\beta_0$ requires sufficient within-unit variation in $X_t$ for all units. This is a very strong condition. Many microeconometric applications are characterized by a preponderance of stayers.\textsuperscript{14} While time series variation in $X_t$ is essential for identification, persistence in its process is common in practice. This persistence may imply that the right-hand side of (12) is undefined.

1.3. Irregular Identification

In this section, we show that, under weak conditions, $\delta_0$ and $\beta_0$ are irregularly identified when $T = p$. We show how to extend our methods to the irregular $T > p$ (overidentified) case in Section 3 below. Let $D = \det(X)$ and $X^* = \text{adj}(X)$, respectively, denote the determinant and adjoint of $X$ such that $X^{-1} = \frac{1}{D}X^*$ when the former exists.\textsuperscript{15} In what follows, we often refer to units where $D = 0$ as stayers. To motivate this terminology consider the case where $T = p = 2$ with $W$ and $X$ in (9) equal to

$$W = \begin{pmatrix} 0 \\ 1 \end{pmatrix}, \quad X = \begin{pmatrix} 1 & X_1 \\ 1 & X_2 \end{pmatrix},$$

with $X_t$ scalar. This corresponds to a model with (i) a random intercept and slope coefficient, and (ii) a common intercept shift between periods one and two. In this model,

$$D = X_2 - X_1 = \Delta X;$$

hence $D = 0$ corresponds to $\Delta X = 0$ or a unit’s value of $X_t$ staying fixed across the two periods. More generally, $D = 0$ if two or more rows of $X$ coincide, which occurs if $X_t$ does not change across adjacent periods or reverts to an earlier value in a later period. Loosely speaking, we may think of stayers as units whose value of $X_t$ changes little across periods.

Let $Y^* = X^*Y$ and $W^* = X^*W$ equal $Y$ and $W$ after premultiplication by the adjoint of $X$. In the $T = p = 2$ example introduced above, we have

$$X^* = \begin{pmatrix} X_2 & -X_1 \\ -1 & 1 \end{pmatrix}, \quad Y^* = \begin{pmatrix} X_2Y_1 - X_1Y_2 \\ \Delta Y \end{pmatrix}, \quad W^* = \begin{pmatrix} -X_1 \\ 1 \end{pmatrix}.$$

In an abuse of notation let $\beta_0(d) = \mathbb{E}[\beta_0(X) | D = d]$. Our identification result, in addition to (9), requires the following assumption.

\textsuperscript{14}In Card’s (1996, Table V, p. 971) analysis of the union wage premium, for example, less than 10 percent of workers switch between collective bargaining coverage and noncoverage across periods.

\textsuperscript{15}The adjoint matrix of $A$ is the transpose of its cofactor matrix.
ASSUMPTION 1.2—Smoothness and Continuity:

(i) For some $u_0 > 0$, $D = \det(X)$ has $\Pr(|D| < h) = \int_{-h}^{h} \phi(u) \, du$ with $\phi(u) > 0$ for all $h \leq u_0$.

(ii) $\mathbb{E}[\|W^*\|^2] < \infty$ and $\mathbb{E}[W^*W^*|D = 0]$ is nonsingular.

(iii) The functions $\beta_0(u)$, $\phi(u)$, $\mathbb{E}[W^*|D = u]$, and $\mathbb{E}[W^*W^*|D = u]$ are all twice continuously differentiable in $u$ for $-u_0 \leq u \leq u_0$.

Part (i) of Assumption 1.2 is essential as our approach involves conditioning on different values of $D$. While the requirement that $D$ has positive density near zero is indispensable, the implication that $\Pr(D = 0) = 0$ can be relaxed. In Section 3, we show how to deal with the case where the distribution $D$ has a point mass at zero. This may occur if the distribution of $X_t$ has mass points at a finite set of values, while being continuously distributed elsewhere. If there is overlap in the mass points of $X_t$ and $X_s$ ($t \neq s$), then the distribution of $D$ will have a mass point at zero.

Part (ii) of Assumption 1.2 is required for identification of $\delta_0$. It will typically hold in well specified models and is straightforward to verify. Part (iii) is a smoothness assumption that, in conjunction with (i), allows us to trim without changing the estimand.

Identification of the Aggregate Time Effects, $\delta_0$

We begin by premultiplying (9) by $X^*$ to get

$$\mathbb{E}[Y^*|X] = W^*\delta_0 + D\beta_0(X),$$

where we use the fact that $DI_T = X^*X$. Conditioning on the subpopulation of stayers yields

$$\mathbb{E}[Y^*|X, D = 0] = W^*\delta_0. \tag{17}$$

Under Assumption 1.2, equation (17) implies that $\delta_0$ is identified by the conditional linear predictor (CLP)

$$\delta_0 = \mathbb{E}[W^*W^*|D = 0]^{-1} \times \mathbb{E}[W^*Y^*|D = 0]. \tag{18}$$

Equation (18) shows that the subpopulation of stayers, or “within-stayer” variation, is used to tie down the aggregate time effects, $\delta_0$. Since stayer’s correspond to units whose values of $X_t$ change little over time, the evolution of $Y_t$ among these units is driven solely by the aggregate time effects. This approach to identifying $\delta_0$ is reminiscent of Chamberlain’s (1986, p. 205), “identification at infinity” result for the intercept of the censored regression model. Both approaches use a small subpopulation to tie down a feature of the entire population. An important difference is that our result does not require $X_t$ to have unbounded support. Consequently, our identification result is not sensitive to
the tail properties of the distribution of $X$. Our key requirement, that $D$ have positive density in a neighborhood about zero, is straightforward to verify. We do this in the empirical application by plotting a kernel density estimate of $\phi(d)$, the density of $D$ (see Figure 1 in Section 4).

In the $T = p = 2$ example, we have, conditional on $D = 0$, the equality $Y^* = W^* \Delta Y$, so that (18) simplifies to, recalling that $D = \Delta X$,

$$\delta_0 = \mathbb{E}[\Delta Y|\Delta X = 0].$$

The common intercept shift is identified by the average change in $Y_t$ in the subpopulation of stayers. Identification of $\delta_0$ is irregular since $\Pr(D = 0) = 0$; $\delta_0$ corresponds to the value of the nonparametric mean regression of $\Delta Y$ given $D$ at $D = 0$. Note the importance of the (verifiable) requirement that $\phi(0) > 0$ for this result.

As a second example of (18), consider the one period panel data model introduced above. From (16), we have

$$\mathbb{E}[Y|X = 0] = \delta_0$$

or identification at zero.

**Identification of the Average Partial Effects, $\beta_0$**

Treating $\delta_0$ as known, we identify $\beta_0(x)$ for all $x$ such that $d$ is nonzero by

$$\beta_0(x) = \mathbb{E}[X^{-1}(Y - W\delta_0)|X = x].$$

It is instructive to consider the $T = p = 2$ case introduced above. In that model, the second component of the right-hand side of (20), corresponding to the slope coefficient on $X_t$, evaluates to

$$\beta_{20}(x) = \frac{\mathbb{E}[\Delta Y|X = x] - \delta_0}{x_2 - x_1} = \frac{\mathbb{E}[\Delta Y|X = x] - \mathbb{E}[\Delta Y|\Delta X = 0]}{x_2 - x_1},$$

where the second, difference-in-differences, equality follows by substituting in (19) above. Equation (21) indicates that the average slope coefficient in a subpopulation homogenous in $X = x$ is equal to the average rise—$\mathbb{E}[\Delta Y|X = x]$—over the common run—$x_2 - x_1$. The evolution of $Y_t$ among stayers is used to eliminate the aggregate time effect from the average rise (i.e., to control for common trends) in this computation. Stayers serve as the control group.

Using (21), we then might try, by appealing to the law of iterated expectations, to identify $\beta_{20}$ by

$$\mathbb{E} \left[ \frac{\Delta Y - \delta_0}{\Delta X} \right].$$
An approach based on (22) was informally suggested by Mundlak (1961, p. 45). Chamberlain (1982) considered (22) with \( \delta_0 = 0 \), showing that it identifies \( \beta_{20} \) if \( E[|\Delta Y/\Delta X|] < \infty \). However, if \( \Delta X \) has a positive, continuous density at zero and if \( E[|\Delta Y|/\Delta X = d] - \delta_0 \) does not vanish at \( d = 0 \), then (22) will not be finite. For example, if \( \Delta Y \) and \( \Delta X \) are independently and identically distributed according to the standard normal distribution, then \( \Delta Y/\Delta X \) will be distributed according to the Cauchy distribution, whose expectation does not exist.

More generally, the expectation

\[ E[X^{-1}(Y - W\delta_0)] \]

will be generally undefined if the distribution of \( X \) is such that \( D \) has a positive density in the neighborhood of \( D = 0 \) (i.e., there is a positive density of stayers). This will occur when, for example, at least two rows of \( X \) nearly coincide for enough units (i.e., when part (i) of Assumption 1.2 holds).

To deal with the small denominator effects of stayers, we trim. Under parts (i) and (iii) of Assumption 1.2, we have the equalities (see equation (41) in the Appendix)

\[
\beta_0 = E[\beta_0(X)] = \lim_{h \to 0} E[\beta_0(X) \cdot 1(|D| > h)] = \lim_{h \to 0} E[X^{-1}(Y - W\delta_0) \cdot 1(|D| > h)],
\]

so that \( \beta_0 \) is identified by the limit of the trimmed mean of \( X^{-1}(Y - W\delta_0) \). Trimming eliminates those units with near-singular design matrices (i.e., stayers); by taking limits and exploiting continuity, we avoid changing the estimand.

Note that if there is a point mass of stayers such that \( \Pr(D = 0) = \pi_0 > 0 \), then (23) does not equal \( \beta_0 \); instead it equals

\[
\beta_0^M = E[\beta_0(X)|D \neq 0]
\]

or the movers average partial effect (MAPE). Let \( \beta_0^S = E[\beta_0(X)|D = 0] \) equal the corresponding stayers average partial effect (SAPE). In Section 3, we show how to extend our results to identify the full average partial effect \( \beta_0 = \pi_0\beta_0^S + (1 - \pi_0)\beta_0^M \) in this case.

The following proposition, which is proven in the Appendix as a by-product of the consistency part of Theorem 2.1 below, summarizes our main identification result.

**Proposition 1.2**—Irregular Identification: Suppose that (i) \( (F_0, \delta_0, \beta_0(\cdot)) \) satisfies (9), (ii) \( \Sigma(x) \) is positive definite for all \( x \in \mathbb{R}^T \), (iii) \( T = p \), and (iv) Assumption 1.2 holds. Then \( \delta_0 \) and \( \beta_0 \) are identified, respectively, by (18) and (23).
2. ESTIMATION

Our approach to estimation is to replace (18) and (23) with their sample analogs. We begin by discussing our estimator for the common parameters $\delta_0$. Let $h_N$ denote some bandwidth sequence such that $h_N \to 0$ as $N \to \infty$. We estimate $\delta_0$ by the nonparametric conditional linear predictor fit

\[
\hat{\delta} = \left[ \frac{1}{Nh_N} \sum_{i=1}^{N} \mathbf{1}(|D_i| \leq h_N) \mathbf{W}^*_i \mathbf{W}^*_i \right]^{-1} \times \left[ \frac{1}{Nh_N} \sum_{i=1}^{N} \mathbf{1}(|D_i| \leq h_N) \mathbf{W}^*_i \mathbf{Y}^*_i \right].
\]

Observe that $\hat{\delta}$ may be computed by a least squares fit of $Y^*_i$ onto $W^*_i$ using the subsample of units for which $|D_i| \leq h_N$. This estimator has asymptotic properties similar to a standard (uniform) kernel regression fit for a one-dimensional problem. In particular, in the proof to Lemma A.2 in the Appendix, we show that

\[
\text{Var}(\hat{\delta}) = O\left( \frac{1}{Nh_N} \right) \gg O\left( \frac{1}{N} \right),
\]

so that its mean squared error (MSE) rate of convergence is slower than $1/N$ when $h_N \to 0$. We also show that the leading bias term in $\hat{\delta}$ is quadratic in the bandwidth so that the fastest rate of convergence of $\hat{\delta}$ to $\delta_0$ will be achieved when the bandwidth sequence is of the form

\[
h^*_N \propto N^{-1/5}.
\]

To center the limiting distribution of $\sqrt{Nh_N}(\hat{\delta} - \delta_0)$ at zero, we use a bandwidth sequence that approaches zero faster than the MSE-optimal one. We discuss our chosen bandwidth sequence in more detail below.

With $\hat{\delta}$ in hand, we then estimate $\beta_0$ using the trimmed mean\(^{16}\)

\[
\hat{\beta} = \frac{1}{N} \sum_{i=1}^{N} \mathbf{1}(|D_i| > h_N) \mathbf{X}_i^{-1} (\mathbf{Y}_i - \mathbf{W}_i \hat{\delta}) .
\]

\(^{16}\)The denominator in (25) could be replaced by 1.
To derive the asymptotic properties of $\hat{\beta}$, we begin by considering those of the infeasible estimator based on the true value of the time effects, $\delta_0$:

$$\hat{\beta}_I = \frac{1}{N} \sum_{i=1}^{N} \mathbf{1}(|D_i| > h_N)^{-1}(Y_i - W_i \delta_0).$$

(26)

Like $\hat{\delta}$, the variance of $\hat{\beta}_I$ is of order $1/Nh_N$; however, its asymptotic bias is linear, not quadratic, in $h_N$. The fastest feasible rate of convergence of $\hat{\beta}_I$ to $\beta_0$ is consequently slower than that of $\hat{\delta}$ to $\delta_0$ ($N^{-2/3}$ versus $N^{-4/5}$). To center the limiting distribution of $\sqrt{Nh_N}(\hat{\beta}_I - \beta_0)$ at zero, we assume that $(Nh_N)^{1/2}h_N \to 0$ as $N \to \infty$. This is stronger than what is needed to appropriately center the distribution of the aggregate time effects, where assuming $(Nh_N)^{1/2}h_2 \to 0$ as $N \to \infty$ would suffice.

The value of studying the large sample properties of $\sqrt{Nh_N}(\hat{\beta}_I - \beta_0)$ is that our feasible estimator is a linear combination of $\hat{\beta}_I$ and $\hat{\delta}$:

$$\hat{\beta} = \hat{\beta}_I + \hat{\Xi}_N(\hat{\delta} - \delta_0),$$

(27)

with

$$\hat{\Xi}_N = \frac{1}{N} \sum_{i=1}^{N} \mathbf{1}(|D_i| > h_N)D_i^{-1}W_i.$$  

(28)

Note that $\hat{\beta}_I$ and $\hat{\delta}$ are, respectively, computed using the $|D_i| > h_N$ and $|D_i| \leq h_N$ subsamples, so they are conditionally independent given the $\{X_i\}$. This independence exploits the fact that the same bandwidth sequence is used to estimate $\hat{\delta}$ and $\hat{\beta}$; it also results from our choice of the uniform kernel, which has bounded support. We proceed under these maintained assumptions, acknowledging that it means that the rate of convergence of $\hat{\delta}$ to $\delta_0$ is well below optimal. We view the gains from using the same bandwidth sequence for both $\hat{\delta}$ and $\hat{\beta}$—in terms of simplicity and transparency of asymptotic analysis—as worth the cost in generality. This approach has the further advantage in that it allows for the effect of sampling error in $\hat{\delta}$ on that of $\hat{\beta}$ to be easily characterized.

Lemma A.3 in the Appendix shows that

$$\hat{\Xi}_N \xrightarrow{p} \Xi_0 = \lim_{h \downarrow 0} \mathbb{E}[\mathbf{1}(|D_i| > h)D_i^{-1}W_i].$$
We therefore recover the limiting distribution of the feasible estimator \( \hat{\beta} \) from our results on \( \hat{\beta}_I \) and \( \hat{\delta} \) using a delta method type argument based on (27).

To formalize the above discussion and provide a precise result, we require the following additional assumptions.

**Assumption 2.1—Random Sampling:** \( \{(Y_i, X_i)\}_{i=1}^N \) are i.i.d. draws from a distribution \( F_0 \) that satisfies condition (9) above.

**Assumption 2.2—Bounded Moments:** \( \mathbb{E}[\|X_i^* Y_i\|^4 + \|X_i^* W_i\|^4] < \infty \).

**Assumption 2.3—Smoothness:** The conditional expectations \( \beta_0(u), \mathbb{E}[X^* \Sigma(X)X^*|D = u], \) and \( m_r(u) = \mathbb{E}[\|X_i^* Y_i\|^r + \|X_i^* W_i\|^r|D = u] \) exist and are twice continuously differentiable for \( u \) in a neighborhood of zero and \( 0 \leq r \leq 4 \).

**Assumption 2.4—Local Identification:** \( \mathbb{E}[X^* \Sigma(X)X^*|D = 0] \) is positive definite.

**Assumption 2.5—Bandwidth:** As \( N \to \infty \), we have \( h_N \to 0 \) such that \( Nh_N \to \infty \) and \( (Nh_N)^{1/2}h_N \to 0 \).

Assumption 2.1 is a standard random sampling assumption. Our methods could be extended to consider other sampling schemes in the usual way. Assumptions 2.2 and 2.3 are regularity conditions that allow for the application of Liapunov’s central limit theorem for triangular arrays (e.g., Serfling (1980)). Assumption 2.5 is a bandwidth condition that ensures that \( \sqrt{Nh_N}(\hat{\beta} - \beta_0) \) is asymptotically centered at zero with a finite variance as discussed below.

The smoothness imposed by Assumption 2.3 can be restrictive. For example, if \( T = p = 2 \) with \( X = (1, X_1)^T \), and \( X_1 \) and \( X_2 \) independent exponential random variables with parameter \( 1/\lambda \), then \( D = \Delta X \) will be a Laplace \((0, \lambda)\) random variable (the density of which is nondifferentiable at zero). Nondifferentiability of the density of \( D \) at \( D = 0 \) will prevent us from consistently estimating the common time effects, \( \delta \) (and, consequently, also \( \beta_0 \)).\(^{17}\) To gauge the restrictiveness of Assumption 2.3, note that twice continuous differentiability is required for nonparametric kernel estimation of, for example, \( \phi(u) \) and \( \mathbb{E}[W^*|D = u] \), and is, consequently, a standard assumption in the literature on nonparametric density and conditional moment estimation (e.g., Pagan and Ullah (1999, Chapters 2 and 3)).

**Theorem 2.1—Large Sample Distribution:** Suppose that (i) \( (F_0, \delta_0, \beta_0(\cdot)) \) satisfies (9), (ii) \( \Sigma(x) \) is positive definite for all \( x \in \mathbb{R}^T \), (iii) \( T = p \), and (iv) As-

\(^{17}\)More precisely it will invalidate our proof.
sumptions 1.2–2.5 hold, then \( \hat{\delta} \overset{p}{\to} \delta_0 \) and \( \hat{\beta} \overset{p}{\to} \beta_0 \) with the normal limiting distribution

\[
\sqrt{Nh_N} \left( \begin{array}{c} \hat{\delta} - \delta_0 \\ \hat{\beta} - \beta_0 \end{array} \right) \overset{D}{\to} \mathcal{N}(0, \Omega_0),
\]

\[
\Omega_0 = \left( \begin{array}{cc} \Lambda_0/2\phi_0 & \Lambda_0 \Xi' \phi_0 \\ \Xi_0 \Lambda_0 & 2\gamma_0 \phi_0 + \Xi_0 \Lambda_0 \Xi' \phi_0/2\phi_0 \end{array} \right),
\]

where

\[
\Lambda_0 = \mathbb{E}[W^* W^* | D = 0]^{-1} \mathbb{E}[W^* X^* \Sigma(X) X^* W^* | D = 0] \\
\quad \times \mathbb{E}[W^* W^* | D = 0]^{-1},
\]

\[
\gamma_0 = \mathbb{E}[X^* \Sigma(X) X^* | D = 0].
\]

We comment that, in contrast to the irregularly identified semiparametric models discussed in Heckman (1990), Andrews and Schafgans (1998), and Khan and Tamer (2010), the rate of convergence for our estimator does not depend on delicate “relative tail conditions.” Our identification approach is distinct from the type of “identification and infinity” arguments introduced by Chamberlain (1986) and leads to a somewhat simpler asymptotic analysis.

Ex ante, that the rate of convergence of \( \hat{\delta} \) and \( \hat{\beta} \) coincide, might be considered surprising. While \( \hat{\delta} \) is based on an increasingly smaller fraction of the sample as \( N \to \infty \), \( \hat{\beta} \) is based on an increasingly larger fraction. However, the latter estimate increasingly includes high variance observations (i.e., units with \( D \) close to zero) as \( N \to \infty \). The sampling variability induced by the inclusion of these units ensures that, in large enough samples, \( \hat{\beta} \)’s variance is of order \( 1/Nh_N \).

It is instructive to compare the asymptotic variances given in Theorem 2.1 with Chamberlain’s regular counterparts (given in (14) and (15) above). First consider the asymptotic variance of \( \hat{\delta} \). In our setup, \( W^* \) plays a role analogous to the generalized within-group transformation of \( W \) used by Chamberlain (i.e., \( W_{\delta} = M_{\delta}(X)W \)). Viewed in this light, the form of \( \Lambda_0 \) is similar to that of \( \mathcal{I}(\delta_0)^{-1} \) in the regular case. The key difference is that (i) the expectations in \( \Lambda_0 \) are conditional on \( D = 0 \) (i.e., averages over the subpopulation of stayers) and (ii) the variance of \( \hat{\delta} \) varies inversely with \( \phi_0 \). The greater the density of stayers, the easier it is to estimate \( \hat{\delta} \). We comment that we could estimate \( \hat{\delta} \) more precisely if we replaced (24) with a weighted least squares estimator. We do not pursue this idea here as it would require pilot estimation of \( \Sigma(X) \), a high dimensional object, and hence is unlikely to be useful in practice.
The asymptotic variance of \( \hat{\beta} \) also parallels the form of \( \mathcal{I}(\beta_0)^{-1} \). The first term, \( 2Y_0\phi_0 \), plays the role of \( \mathbb{E}[(X'\Sigma^{-1}(X)X)^{-1}] \) in (15). This term corresponds to the average of the conditional sampling variances of the unit-specific slope estimates. The better is the typical unit-specific design matrix, the greater is the precision of the average \( \hat{\beta} \). In the irregular case, \( 2Y_0\phi_0 \) captures a similar effect. There the average is conditional on \( D = 0 \). In contrast to the aggregate time effects, the first term in the variance of \( \hat{\beta} \) varies linearly with \( \phi_0 \), suggesting that a small density of stayers is better for estimation of \( \beta_0 \).

The second term in \( \hat{\beta}'s \) variance is analogous to the \( K\mathcal{I}(\delta_0)^{-1}K' \) term in (15). This term captures the effect of sampling variation in \( \hat{\delta} \) on that of \( \hat{\beta} \). Note that \( K \) is equal to the average of the \( p \times q \) matrix of coefficients associated with the unit-specific GLS fit of the \( q \times 1 \) vector \( W_t \) given the \( p \times 1 \) vector of regressors \( X_t \). It is instructive to consider an example where there is no asymptotic penalty associated with not knowing \( \delta_0 \).

Chamberlain’s variance bound for \( \beta_0 \) contains a third term, the analog of which is not present in the irregular case. This term, \( \nabla(\beta_0(X)) \), captures the effect of heterogeneity in the conditional average of the random coefficients on the asymptotic variance of \( \hat{\beta} \). In the irregular case, a term equal to \( \nabla(\beta_0(X))/N \) also enters the expression for the sampling variance of \( \hat{\beta} \) (see the calculations immediately prior to Equation (44) in the Appendix). However, this term is asymptotically dominated by the two terms listed in Theorem 2.1 (which are of order \( 1/Nh_N \)). The variance estimator described in Theorem 2.2 below implicitly accounts for this asymptotically dominated component.

18 Sampling error in the estimated time effects does affect the precision with which the common intercept, the first component of \( \beta_0 \), can be estimated.
The conditions of Theorem 2.1 place only weak restrictions on the bandwidth sequence. As is common in the semiparametric literature, we deal with bias by undersmoothing. Letting \( a \) be a \( p \times 1 \) vector of known constants, the Appendix shows that the fastest rate of convergence of \( a' \hat{\beta} \) for \( a' \beta_0 \) in mean square is achieved by bandwidth sequences of the form

\[
h_N^* = C_0 N^{-1/3},
\]

where the mean squared error minimizing choice of constant is

\[
C_0 = \frac{1}{2} \left( \frac{1}{\phi_0} \right)^{1/3} \left\{ \frac{a' \left( 2 Y_0 + \frac{\Xi_0 \Lambda_0 \Xi'_0}{2 \phi_0^2} \right) a}{a' (\beta_0 - \hat{\beta}_{0}) (\beta_0 - \hat{\beta}_{0})' a} \right\}^{1/3},
\]

(29)

and \( \beta^*_0 = \mathbb{E}[\beta_0(X)|D = 0] \) equals the average of the random coefficients in the subpopulation of stayers. While the bandwidth sequence \( h_N^* \) achieves the fastest rate of convergence for our estimator, the corresponding asymptotic normal distribution for \( a' \hat{\beta}(h_N^*) \) will be centered at a bias term of \( 2 a' (\beta_0 - \beta^*_0) \phi_0 \). To eliminate this bias, Assumption 2.5 requires that \( h_N \to 0 \) fast enough such that \( (Nh_N)^{1/2} \to 0 \) as \( N \to \infty \), but slow enough such that \( (Nh_N)^{1/2} \to \infty \). A bandwidth sequence that converges to zero slightly faster than \( h_N^* \) is sufficient for this purpose. In particular, if

\[
h_N = o(N^{-1/3}),
\]

then \( \sqrt{Nh_N} (\hat{\beta} - \beta_0) \) will be asymptotically centered at zero.

An alternative to undersmoothing would be to use a plug-in bandwidth based on a consistent estimate of (29), say \( \hat{C} \). Such an approach was taken by Horowitz (1992) in the context of smoothed maximum score estimation. Denote the resulting estimate by \( a' \hat{\beta}_{PI} \) (PI for plug-in). Let \( a' \hat{\beta} \) be the consistent undersmoothed estimate of Theorem 2.1, and let \( \hat{\beta}^* \) and \( \hat{\phi}_0 \) be estimates of \( \beta^*_0 \) and \( \phi_0 \). The bias corrected (BC) estimate is then

\[
a' \hat{\beta}_{BC} = a' \hat{\beta}_{PI} - 2 a' (\hat{\beta} - \hat{\beta}^*) \phi_0 \hat{C} N^{-1/3}.
\]

Unlike undersmoothing, this does not slow down the rate of convergence of \( \hat{\beta}_{BC} \) to \( \beta_0 \). A disadvantage is that it is more computationally demanding. In the empirical application below, we experiment with a number of bandwidth values. A more systematic analysis of bandwidth selection, while beyond the scope of this paper, would be an interesting topic for further research.
Computation and Consistent Variance Estimation

The computation of \( \hat{\delta} \) and \( \hat{\beta} \) is facilitated by observing that the solutions to (24) and (25) above coincide with those of the linear instrumental variables fit

\[
\hat{\theta} = \left[ \frac{1}{N} \sum_{i=1}^{N} Q_i R_i \right]^{-1} \times \left[ \frac{1}{N} \sum_{i=1}^{N} Q_i Y_i^* \right]
\]

for \( \theta = (\delta', \beta')' \),

\[
Q_i = \begin{pmatrix} h_N^{-1} 1(|D_i| \leq h_N) W_i^* & \frac{1(|D_i| > h_N)}{D_i} I_p \end{pmatrix},
\]

and

\[
R_i = \begin{pmatrix} W_i^* & 1(|D_i| > h_N) D_i I_p \end{pmatrix},
\]

where the dependence of \( Q_i \) and \( R_i \) on \( h_N \) is suppressed.

Let \( \theta(h) \) denote the probability limit of \( \hat{\theta} \) when the bandwidth is held fixed at \( h \). Then, by standard general method of moments (GMM) arguments,

\[
\hat{V}(h) = \left[ \frac{1}{N} \sum_{i=1}^{N} Q_i R_i \right]^{-1} \times \left[ \frac{h}{N} \sum_{i=1}^{N} Q_i U_i^* U_i^{**} Q_i \right] \times \left[ \frac{1}{N} \sum_{i=1}^{N} Q_i R_i \right]^{-1}
\]

is a consistent estimate of the asymptotic covariance of \( \sqrt{Nh}(\hat{\theta} - \theta(h)) \) with

\[
\hat{U}_i^* = Y_i^* - R_i \hat{\theta}.
\]

Conveniently, this covariance estimator remains valid when, as is required by Theorem 2.1, the bandwidth shrinks with \( N \).

**THEOREM 2.2:** Suppose the hypotheses of Theorem 2.1 hold, that \( \mathbb{E}[\|X_i^* Y_i^*\|^8 + \|X_i^* W_i\|^8] < \infty \), and that Assumption 2.3 holds for \( r \leq 8 \). Then \( \hat{V}_N \equiv \hat{V}(h_N) \xrightarrow{p} \Omega_0 \).

Relative to a direct estimate of \( \Omega_0 \), (30) implicitly includes estimates of terms that, while asymptotically negligible, may be sizeable in small samples. Consequently, confidence intervals constructed using it may have superior properties (cf. Newey (1994b), Graham, Imbens, and Ridder (2009)).

Operationally, estimation and inference may proceed as follows. Let \( Y_{it}^*, R_{it} \), and \( Q_{it} \) denote the \( t \)th rows of their corresponding matrices. Using standard software, compute the linear instrumental variables fit of \( Y_{it}^* \) onto \( R_{it} \) using \( Q_{it} \) as the instrument (exclude the default constant term from this calculation). By Theorem 2.2, the robust/clustered (at the unit level) standard errors reported by the program will be asymptotically valid under the conditions of Theorem 2.1.
3. EXTENSIONS

In this section, we briefly develop four direct extensions of our basic results. In Section 5, we discuss other possible generalizations and avenues for future research.

3.1. Linear Functions of $\beta_0(X)$

In some applications, the elements of $X_t$ may be functionally related. For example,

$X_t = (1, R_t, R_t^2, \ldots, R_t^{p-1})'$.

In such settings, $\beta_0$ indexes the average structural function (ASF) of Blundell and Powell (2003). To emphasize the functional dependence, write $X_t = x_t(R_t)$. Then

$$g_t(\tau) = x_t(\tau)'(\beta_0 + \delta_0t)$$

gives the expected period $t$ outcome if (i) a unit is drawn at random from the (cross-sectional) population and (ii) that unit is exogenously assigned input level $R_t = \tau$. Similarly, differences of the form

$$g_t(\tau') - g_t(\tau)$$

give the average period $t$ outcome difference across two counterfactual policies: one where all units are exogenously assigned input level $R_t = \tau'$ and another where they are assigned $R_t = \tau$. Since it is a linear function of $\beta_0$ and $\delta_0t$, Theorem 2.1 can be used to conduct inference on $g_t(\tau)$.

In the presence of functional dependence across the elements of $X_t$, the derivative of $g_t(\tau)$ with respect to $\tau$ does not correspond to an average partial effect (APE). Instead such derivatives characterize the local curvature of the ASF. In such settings, the average effect of a population-wide unit increase in $R_t$ (i.e., the APE) is instead given by

$$\gamma_{0t} \equiv E \left[ \frac{\partial Y_t(x_t(r_t))}{\partial r_t} \right]$$

$$= E \left[ \left( \frac{\partial x_t(r_t)}{\partial r_t} \right)' b_t(A, U_t) \right]$$

$$= E \left[ \left( \frac{\partial x_t(r_t)}{\partial r_t} \right)' (\beta_0 x_t(R_t) + \delta_0t) \right].$$

$^{19}$We thank a referee for several helpful comments on this point.
where the second equality follows from iterated expectations and Assumption 1.1. Because \( \partial x_t(R_t)/\partial r_t \) may covary with \( \beta_0(x_t(R_t)) \), Theorem 2.1 cannot be directly applied to conduct inference on \( \gamma_{0_t} \). Fortunately, it is straightforward to extend our methods to identify and consistently estimate parameters of the form

\[
\gamma_{0_t} = \mathbb{E}[\Pi(X)(\beta_0(X) + \delta_0)]
\]

where \( \Pi(x) \) is a known function of \( x \) and \( \gamma_0 = \mathbb{E}[\Pi(X)\beta_0(X)] \). If \( X_t \) is given by (31), for example, then to estimate the APE, we would choose

\[
\Pi(x) = \frac{\partial x_t(r_t)}{\partial r_t} = (0, 1, 2r_t, 3r_t^2, \ldots, (p - 1)r_t^{p-2}).
\]

To estimate \( \gamma_{0_t} \), we proceed as follows. First, identification and estimation of \( \delta_0 \) is unaffected. Second, using (20) gives, for any \( x \) with \( d \neq 0 \),

\[
\gamma_0(x) = \Pi(x)\mathbb{E}[X^{-1}(Y - W\delta_0)|X = x],
\]

so that

\[
\gamma_0 = \lim_{h \to 0} \mathbb{E}[\Pi(X)X^{-1}(Y - W\delta_0) \cdot 1(|D| > h)].
\]

This suggests the analog estimator

\[
\hat{\gamma} = \frac{1}{N} \sum_{i=1}^{N} 1(|D_i| > h_N)\Pi(X_i)X_i^{-1}(Y_i - W\hat{\delta})
\]

An argument essentially identical to that justifying Theorem 2.1 then gives

\[
(33) \quad \sqrt{Nh_N} \left( \hat{\delta} - \delta_0 \right) \xrightarrow{D} \mathcal{N} \left( 0, \begin{pmatrix} \frac{\Lambda_0}{2\phi_0} & \frac{\Lambda_0\Xi_{\Pi,0}}{2\phi_0} \\ \frac{\Xi_{\Pi,0}\Lambda_0}{2\phi_0} & 2Y_{\Pi,0}\phi_0 + \frac{\Xi_{\Pi,0}\Lambda_0\Xi_{\Pi,0}}{2\phi_0} \end{pmatrix} \right).
\]

\[20\] It is possible that while \( \beta_0 \) is only irregularly identified, \( \mathbb{E}[\Pi(X)\beta_0(X)] \) is regularly identified. Consider the \( T = p = 2, q = 1 \) example introduced above. If \( \Pi(X) = (1, X_1) \), then \( \mathbb{E}[\Pi(X)\beta_0(X)] = \mathbb{E}[\mathbb{E}[Y_1|X]] = \mathbb{E}[Y_1] \) is clearly regularly identified. What follows, for simplicity, assumes that \( \mathbb{E}[\Pi(X)\beta_0(X)] \) is not regularly identified.
with
\[ Y_{it,0} = \mathbb{E}[\Pi(X)X^\prime\Sigma(X)X^\prime\Pi(X) | D = 0], \]
\[ \Xi_{it,0} = \lim_{h \downarrow 0} \mathbb{E}[1(|D| > h)\Pi(X)X^{-1}W]. \]

We can then estimate \( \gamma_{0t} \) by
\[ \hat{\gamma}_t = \hat{\gamma} + \hat{\Pi}\hat{\delta}, \]
with \( \hat{\Pi} = \sum_{i=1}^{N} \Pi(X_i)/N. \) To conduct inference on \( \gamma_{0t} \), we use the delta method, treating \( \hat{\Pi} \) as known. We can ignore the effects of sampling variability in \( \hat{\Pi} \) since its rate of convergence to \( \mathbb{E}[\Pi(X)] \) is \( 1/N. \)

3.2. Density of \( D \) Has a Point Mass at \( D = 0 \)

In some settings, a positive fraction of the population may be stayers such that \( \pi_0 \equiv \text{Pr}(D = 0) > 0. \) This may occur even if all elements of \( X_i \) are continuously valued. If the only continuous component of \( X_i \) is the logarithm of annual earnings, for example, a positive fraction of individuals may have the same earnings level in each sampled period. This may be especially true if many workers are salaried.

A point mass at \( D = 0 \) simplifies estimation of \( \delta_0 \) and complicates that of \( \beta_0. \) When \( \pi_0 > 0, \) the estimator
\[ \hat{\delta} = \left[ \frac{1}{N} \sum_{i=1}^{N} 1(D_i = 0)W_i^\prime W_i \right]^{-1} \times \left[ \frac{1}{N} \sum_{i=1}^{N} 1(D_i = 0)W_i^\prime Y_i \right] \]
will be \( \sqrt{N} \)-consistent and asymptotically normal for \( \delta_0, \) as would be the (asymptotically equivalent) estimator described in Section 2 above.

The large sample properties of the infeasible estimator \( \hat{\beta} \) (see Equation (26)) are unaffected by the point mass at \( D = 0 \) with two important exceptions. First, its probability limit is no longer \( \beta_0, \) the (full population) average partial effect, but \( \beta_0^M = \mathbb{E}[\beta_0(X)|D \neq 0], \) the movers’ APE introduced in Section 1. Second, its asymptotic variance is scaled up by \( 1 - \pi_0, \) the population proportion of movers. This gives \( \sqrt{Nh_N}(\hat{\beta} - \beta_0^M) \xrightarrow{D} \mathcal{N}(0, \frac{2\gamma_0\phi_0}{1-\pi_0}). \)

Reflecting the change of plims, let \( \hat{\beta}_M \) equal the feasible estimator defined by (25). Using decomposition (27), we have
\[ \sqrt{Nh_N}(\hat{\beta}_M - \beta_0^M) = \sqrt{Nh_N}(\hat{\beta}_I - \beta_0^M) + \Xi_N\sqrt{Nh_N}(\hat{\delta} - \delta_0) \]
\[ = \sqrt{Nh_N}(\hat{\beta}_I - \beta_0^M) + \Xi_0O_p(\sqrt{h_N}) \]
\[ = \sqrt{Nh_N}(\hat{\beta}_I - \beta_0^M) + o_p(1), \]
so that the sampling properties of $\hat{\beta}^M$ are unaffected by those of $\hat{\delta}$. In particular, adapting the argument used to show Theorem 2.1 yields
\[
\sqrt{Nh_N(\hat{\beta}^M - \beta_0^M)} \overset{D}{\to} N\left(0, \frac{2Y_0\phi_0}{1 - \pi_0}\right).
\]

If a consistent estimator of the stayers effect
\[
\beta_0^S \equiv \mathbb{E}[\beta_0(X)|D = 0]
\]
can be constructed, a corresponding consistent estimator of the APE $\beta_0 = \pi_0\beta_0^S + (1 - \pi_0)\beta_0^M$ would be
\[
\hat{\beta} \equiv \hat{\pi}\hat{\beta}^S + (1 - \hat{\pi})\hat{\beta}^M,
\]
where $\hat{\pi} \equiv \sum_{i=1}^{N} 1(|D_i| \leq h_N)/N$ is a $\sqrt{N}$-consistent estimator for $\pi_0$.

Inspection of the equation immediately preceding (17) in Section 1 suggests one possible estimator for $\beta_0^S$. We have
\[
\mathbb{E}[Y^*|X] = W^*\delta_0 + D\beta_0(X),
\]
so that
\[
\beta_0^S = \lim_{h \to 0} \frac{\mathbb{E}[Y^*|D = h] - \mathbb{E}[Y^*|D = 0]}{h},
\]
which suggests the estimator
\[
\left(\hat{\delta}, \hat{\beta}\right) = \arg\min_{\delta, \beta} \sum_{i=1}^{N} 1(|D_i| \leq h_N)(Y_i^* - W_i^*\delta - D_i\beta)^S',
\]
\[
\times (Y_i^* - W_i^*\delta - D_i\beta)^S,
\]
with $\hat{\delta}$ an alternative $\sqrt{N}$-consistent estimator for $\delta_0$. Since the rate of convergence of a nonparametric estimator of the derivative of a regression function is lower than for its level, the rate of convergence of the combined estimator $\hat{\beta} \equiv \hat{\pi}\hat{\beta}^S + (1 - \hat{\pi})\hat{\beta}^M$ will coincide with that of $\hat{\beta}^S$, and the asymptotic distribution of the latter would dominate the asymptotic distribution of $\hat{\beta}$ in this setting. We comment that part (iii) of Assumption 1.2 may be less plausible in settings where $\Pr(D = 0) > 0$.\(^{21}\) It such settings, stayers may be very different from near-stayers such that a local linear regression approach to estimating $\hat{\beta}^S$ would be problematic.

\(^{21}\) We thank a referee for this observation.
3.3. Overidentification ($T > p$)

When $T > p$, the vector of common parameters $\delta_0$ may be $\sqrt{N}$ consistently estimated, as first suggested by Chamberlain (1992), by the sample counterpart of (11) above:

$$
\hat{\delta} = \left[ \frac{1}{N} \sum_{i=1}^{N} \bar{W}_{\phi_i} \phi_i \bar{W}_{\phi_i} \right]^{-1} \times \left[ \frac{1}{N} \sum_{i=1}^{N} \bar{W}_{\phi_i} \phi_i \bar{W}_{\phi_i} \right],
$$

with $\phi_i \equiv \phi(X_i)$ positive definite with probability 1.

The discussion in Section 1, however, suggests that Chamberlain’s (1992) proposed estimate of $\beta_0$, the sample average of

$$
\hat{\beta}_i \equiv (X_i' \phi_i^{-1} X_i)^{-1} X_i' \phi_i^{-1} (Y_i - W_i \hat{\delta})
$$

for $\hat{\delta}$ a $\sqrt{N}$-consistent estimator of $\delta_0$, may behave poorly and will be formally inconsistent when $I(\beta_0) = 0$.

Adapting the trimming scheme introduced for the just identified $T = p$ case, a natural modification of Chamberlain’s (1992) estimator is

$$
\hat{\xi} = \frac{\sum_{i=1}^{N} I(\det(X_i' \phi_i^{-1} X_i) > h_N) \cdot (X_i' \phi_i^{-1} X_i)^{-1} X_i' \phi_i^{-1} (Y_i - W_i \hat{\delta})}{\sum_{i=1}^{N} I(\det(X_i' \phi_i^{-1} X_i) > h_N)}.
$$

If

$$(34) \quad \mathbb{E} \left[ \frac{1}{\det(X_i' \phi_i^{-1} X_i)} \right] < \infty,$$

then the introduction of trimming is formally unnecessary but may still be helpful in practice. It is straightforward to show asymptotic equivalence of the (infeasible) trimmed mean

$$
\hat{\xi} = \frac{\sum_{i=1}^{N} I(\det(X_i' \phi_i^{-1} X_i) > h_N) \cdot (X_i' \phi_i^{-1} X_i)^{-1} X_i' \phi_i^{-1} (Y_i - W_i \hat{\delta}_0)}{\sum_{i=1}^{N} I(\det(X_i' \phi_i^{-1} X_i) > h_N)}
$$

with Chamberlain’s (1992) proposal when $\mathbb{E}[\beta(X) | \det(X_i' \phi_i^{-1} X_i) \leq h]$ is smooth (Lipschitz continuous) in $h$, condition (34) holds, and $h_N = o(1/\sqrt{N})$. 

Since $\hat{\beta}$ will still be consistent for $\beta$ even when (34) fails, a feasible version of the trimmed mean $\hat{\beta}$ may be better behaved in finite samples if the design matrix $(X_i'\Phi_i^{-1}X_i)$ is nearly singular for some observations.

3.4. Additional Regressors

Our benchmark model assumes that $W$ is a known function of $X$. Let $V$ be a $T \times r$ matrix of additional regressors and assume that, in place of (9), we have the conditional moment restriction

\begin{equation}
E[Y|X, V] = V_0 + X_0 \delta_0 + X_0 \beta_0,
\end{equation}

Such a model might arise if, instead of (1), we have

\begin{equation}
Y_t = V_t' \zeta_0 + X_t' \beta_0 + (A_t, U_t),
\end{equation}

with $V_t$ varying independently of $(A_t, U_t)$.

Assume that $V_t = V - E[V|X]$ has a covariance matrix of full rank. Following Engle et al. (1986), we have

$$
\zeta_0 = E[\tilde{V} \tilde{V}]^{-1} \times E[\tilde{V} Y],
$$

which, under regularity conditions, is also $\sqrt{N}$ estimable (e.g., Robinson (1988)). Letting $\hat{\zeta}$ be such a consistent estimate, we may proceed as described in Section 2 after replacing $Y$ with $Y - V \hat{\zeta}$. Since the rate of convergence of $\hat{\zeta}$ to $\zeta_0$ is $1/N$, we conjecture that Theorem 2.1 will remain valid with $\Sigma(X)$ redefined to equal $V(Y - V \zeta_0|X)$. Model (35) indicates that while the feasible number of random coefficients is restricted by the length of the available panel, the overall number of regressors need not be.

4. APPLICATION

In this section, we use our methods to estimate the elasticity of calorie demand using the panel data set described in the introduction. Our goal is to provide a concrete illustration of our methods, to compare them with alternatives that presume the absence of any nonseparable correlated heterogeneity, and to highlight the practical importance of trimming.

Model Specification

We assume that the logarithm of total household calorie availability per capita in period $t$, $\ln(\text{Cal}_t)$, varies according to

\begin{equation}
\ln(\text{Cal}_t) = b_{0t}(A, U_t) + b_{1t}(A, U_t) \ln(\text{Exp}_t),
\end{equation}

where $\text{Exp}_t$ denotes real household expenditure per capita (in thousands of 2001 cordobas) in year $t$, and $b_{0t}(A, U_t)$ and $b_{1t}(A, U_t)$ are random coefficients; the latter equals the household-by-period-specific elasticity of calorie demand. Let $b_t(A, U_t) = (b_{0t}(A, U_t), b_{1t}(A, U_t))'$, $X_t = (1, \ln(\text{Exp}_t))'$, and
\[ Y_t = \ln(\text{Cal}_t) \] with \( \mathbf{X} \) and \( \mathbf{Y} \) as defined above. We allow for common intercept and slope shifts over time (i.e., we maintain Assumption 1.1).

Relative to prior work, the distinguishing feature of our model is that it allows for the elasticity of calorie demand to vary across households in a way that may covary with total outlay. This allows household expenditures to covary with the unobserved determinants of calorie demand. For example, both expenditures and calorie consumption are likely to depend on labor supply decisions (cf. Strauss and Thomas (1990)). Allowing the calorie demand curve to vary across households also provides a nonparametric way to control for differences in household composition—a delicate modelling decision in this context (e.g., Subramanian and Deaton (1996)).

**Data Descriptions**

We use data collected in conjunction with an external evaluation of the Nicaraguan conditional cash transfer program Red de Protección Social (RPS) (see International Food Policy Research Institute (IFPRI) (2005)). Here we analyze a balanced panel of 1358 households interviewed in the fall of 2000, 2001, and 2002. We focus on the latter two years of data (see below). The Supplemental Material (Graham and Powell (2012)) describes the construction of our data set in detail.

Tables I and II summarize some key features of our estimation sample. Panel A of Table I give the share of total food spending devoted to each of 11 broad food categories. Spending on staples (cereals, roots, and pulses) accounts for about half of the average household’s food budget and over two-thirds of its calories (Tables I and II). Among the poorest quartile of households, an average of around 55 percent of budgets are devoted to, and over three-quarters of calories available are derived from, staples. Spending on vegetables, fruit, and meat accounts for less than 15 percent of the average household’s food budget and less than 3 percent of calories available. That such a large fraction of calories are derived from staples, while not good dietary practice, is not uncommon in poor households elsewhere in the developing world (cf. Smith and Subandoro (2007)).

Panel B of Table I lists real annual expenditure in cordobas per adult equivalent and per capita. Adult equivalents are defined in terms of age- and gender-specific FAO (2001) recommended energy intakes for individuals engaging in ‘light activity’ relative to prime-aged males. As a point of reference, the 2001 average annual expenditure per capita across all of Nicaragua was a nominal

---

22 A limitation of our model is its presumption of linearity at the household level. Strauss and Thomas (1990) argued that the elasticity of demand should **structurally** decline with household income. As we have three periods of data, we could, in principle, include an additional function of \( \text{Exp}_t \), in the \( \mathbf{X_t} \) vector. We briefly explore this possibility in the Supplemental Material (Graham and Powell (2012)).

a Authors’ calculations are based on a balanced panel of 1358 households from the RPS evaluation data set (IFPRI (2005)). Real household expenditure equals total annualized nominal outlay divided by a Paasche cost-of-living index. Base prices for the price index are 2001 sample medians. The nominal exchange rate in October of 2001 was 13.65 cordobas per U.S. dollar. Total calorie availability is calculated using the RPS food quantity data, and the calorie content and edible portion information contained in INCAP (2000). Lower and upper 25% refer to the bottom and top quartiles of households based on the average of year 2000, 2001, and 2002 real consumption per adult equivalent, and thus contain the same set of households in all 3 years.

b Sum of cereal, roots, and pulses.

c “Adults” correspond to adult equivalents based on FAO (2001) recommended energy requirements for light activity.

d Percentage of households with estimated calorie availability less than FAO (2001) recommendations for light activity given household demographics.

a Authors’ calculations based on a balanced panel of 1358 households from the RPS evaluation data set (see IFPRI (2005)). Total calorie availability is calculated using the RPS food quantity data, and the calorie content and edible portion information contained in INCAP (2000). Lower and upper 25% refer to the bottom and top quartiles of households based on the average of year 2000, 2001, and 2002 real consumption per adult equivalent and thus contain the same set of households in all 3 years.

b Sum of cereal, roots and pulses.

7781 cordobas, while among rural households, it was 5038 cordobas (World Bank (2003)). The 42 communities in our sample, consistent with their participation in an antipoverty demonstration experiment, are considerably poorer than the average Nicaraguan rural community.23

Using the FAO (2001) energy intake recommendations for light activity, we categorized each household, on the basis of its demographic structure, as energy deficient or not. By this criterion, approximately 40 percent of households in our sample are energy deficient each period; among the poorest quartile, this fraction rises to over 75 percent. These figures are reported in panel B of Table I.

Assessment of Required Assumptions

Assumption 1.1 allows us to tie down common time effects using the subpopulation of stayers alone. The appropriateness of using stayers in this way depends on their comparability with movers. Assumption 1.1 will also be more plausible under conditions of relative macroeconomic stability.24

23 In October of 2001, the cordoba to U.S. dollar exchange rate was 13.65. Therefore, per capita consumption levels in our sample averaged less than U.S.$300 per year.

24 Heuristically the hope is that the impacts of any misspecification of aggregate time effects will be muted when such effects are small in magnitude.
With these considerations in mind, we use the 2001 and 2002 waves of RPS data for our core analysis. Coffee production is important in the regions from which our data were collected. While coffee prices fell sharply between the 2000 and 2001 waves of data collection, they were more stable between the 2001 and 2002 waves (see Figure 2 in the Supplemental Material). Panel B of Table I indicates that while per capita household expenditures fell, on average, over 10 percent between 2000 and 2001, they were roughly constant, again on average, between 2001 and 2002.

We also informally compared stayers and near-stayers in terms of observables. Such comparisons provide a heuristic way to assess the plausibility of the assumption that \( \beta(d) \) is smooth in \( d \) in the neighborhood of \( d = 0 \).\(^{25}\) Using the bandwidth value underlying our preferred estimates (see column 5 of Table III and Figure 1), we define stayers as units for which \( D \in [-h_N, h_N] \) and define near-stayers as units for which \( D \in [-1.5h_N, h_N] \) or \( D \in (h_N, 1.5h_N] \). We find that average expenditures across these two sets of households were nearly identical in 2001. We also compared their demographic structures. Across 16 age-by-gender categories, we found significant differences (at the 10 percent level) in 1 category in 2001 and 0 categories in 2002. We conclude that our stayer

\(\text{a}\)Estimates based on the balanced panel of 1358 households described in the main text. OLS denotes least squares applied to the pooled 2000, 2001, and 2002 samples; FE-OLS denotes least squares with household-specific intercepts; R-CRC denotes Chamberlain’s (1992) estimator with identity weight matrix; MDLK denotes the Mundlak (1961)/Chamberlain (1982) estimator described in the main text; and I-CRC denotes our irregular correlated random coefficients estimator (using the 2001 and 2002 waves only). All models, with the exception of MDLK, include common intercept and slope shifts across periods. The standard errors are computed in a way that allows for arbitrary within-village correlation in disturbances across households and time.

\(\text{25}\)The intuition is that if stayers and near-stayers are observationally very different, then it is plausible that the distribution of calorie demand schedules across the two subpopulations also differs.
and near-stayer subsamples are broadly comparable, although we acknowledge that our tests, in addition to being heuristic, are likely to have low power given our available sample size.

The bottom panel of Figure 1 plots a kernel density estimate of the change in ln(Exp$_{ij}$) between 2001 and 2002. As required by Assumption 1.2, there is substantial density in the neighborhood of zero. Furthermore, there is no obvious evidence of a point mass at zero so that, in large samples, the mover and full average partial effects will coincide.

While we took great care in the construction of our expenditure and calories available variables, measurement error in each of them cannot be ruled out. We nevertheless proceed under the maintained assumption of no measurement error. An extension of our methods to accommodate measurement error would be an interesting topic for future research.
Results

Table III reports our point estimates. Our first estimate corresponds to the pooled ordinary least squares (OLS) fit of ln(Cal_t) onto ln(Exp_t) using all three waves of the RPS data. Aggregate shifts in the intercept and slope coefficient are included (throughout we use 2001 as the base year). Also included in the model, to control for variation in food prices across markets, is a vector of 42 village-specific intercepts. Variants of this specification are widely employed in empirical work (e.g., Subramanian and Deaton (1996, Table 2)). The pooled OLS calorie elasticities are reported in column A.1. The elasticity approximately equals 0.7 in 2000 and 0.6 in both 2001 and 2002. All three elasticities are precisely determined. The estimates are high relative to others in the literature, but realistic given the extreme poverty of the households in our sample.

Column A.2 augments the first model by allowing the intercept to vary across households. This fixed effects estimator (FE-OLS) is also widely used in empirical work when panel data are available (e.g., Behrman and Deolalikar (1987), Bouis and Haddad (1992)). Allowing for household-specific intercepts increases the elasticity by about 10 percent in all 3 years. The standard errors almost double in size.

In column A.3, we use Chamberlain’s (1992) regular correlated random coefficients (R-CRC) estimator with an identity weight matrix. Since we have 3 years of data and only two random coefficients, his methods, at least in principle, apply. The top panel of Figure 1 plots a histogram of det(XX'), which shows a reasonable amount of density in the neighborhood of zero. This suggests that the right-hand side of (12) may be undefined in the population. In practice, the R-CRC estimator generates sensible point estimates with estimated standard errors approximately equal to those of the corresponding FE-OLS estimates. The R-CRC point estimates are smaller than both the OLS and FE-OLS estimates. Column B.3 implements the trimmed version of Chamberlain’s procedure described in Section 3 above. In this case, trimming leaves the point estimates more or less unchanged, with a slight increase in their measured precision.

Columns A.4 and A.5 are based only on the 2001 and 2002 waves of data. By dropping the first wave of data, we artificially impose that \( T = p = 2 \); this ensures irregularity (Proposition 1.1). Column A.4 reports the Mundlak estimate of the demand elasticity

\[
\frac{1}{N} \sum_{i=1}^{N} \frac{\ln(Cal_{2002}) - \ln(Cal_{2001})}{\ln(Exp_{2002}) - \ln(Exp_{2001})}.
\]

This average, as expected, is poorly behaved. It generates a much lower elasticity estimate with a very large standard error.

Column A.5 implements our estimator (I-CRC) with a bandwidth of \( h_N = \frac{c_D}{N} \), where \( c_D = \min(s_D, r_D/1.34) \) is a robust estimate of the sample standard deviation of \( D \) (\( s_D \) is the sample standard deviation and \( r_D \) is the
interquartile range). This implies that we trim, or categorize as stayers, about 4 percent of our sample. In contrast to its untrimmed counterpart, the I-CRC point estimate is sensible and well determined. The estimated year 2001 and 2002 elasticities are over 25 percent small than their FE counterparts (column A.2). Panel B of the table explores the sensitivity of our I-CRC point estimates to trimming. We find that doubling the fraction of the sample categorized as stayers substantially improves estimated precision, but also shifts the point estimates upward. Halving the fraction of stayers substantially reduces estimated precision (columns B.1 and B.2). Overall we find that while the column A.5 point estimates are somewhat sensitive to modest variations in the bandwidth, they consistently lie below their FE-OLS counterparts.

5. CONCLUSION

In this paper, we have outlined a new estimator for the correlated random coefficients panel data model. Our estimator is designed for situations where the regularity conditions required for the method-of-moments procedure of Chamberlain (1992) do not hold. We illustrate the use of our methods in a study of the elasticity of demand for calories in a population of poor Nicaraguan households. This application is highly irregular, with many near-stayers in the sample. This implies that elasticity estimates based on the textbook FE-OLS estimator may be far from the relevant population average. We find that our methods work well in this setting, generating point estimates that are as much as 25 percent smaller in magnitude that their FE-OLS counterparts (Table III, column A.5 versus A.2).

While our procedure is simple to implement, it does require choosing a smoothing parameter. As in other areas of semiparametric econometrics, our theory places only weak restrictions on this choice. Developing an automatic, data-based method of bandwidth selection would be useful.

Irregularity arises in other fixed effects panel data models (e.g., Manski (1987), Chamberlain (2010), Honoré and Kyriaizidou (2000), Kyriaizidou (1997), Hoderlein and White (2009)). It is an open question as to whether features of our approach could be extended to more complex nonlinear and/or dynamic panel data models. In ongoing work, we are studying how to extend our methods to estimate quantile partial effects (e.g., unconditional quantiles of the distribution of the random coefficients) and to accommodate additional triangular endogeneity.

26This bandwidth value corresponds to Silverman’s well known normal reference rule-of-thumb bandwidth for density estimation. We divide by 2 to adjust for the fact that our uniform kernel integrates to 2 instead of 1.
APPENDIX A

This appendix contains a proof of Theorem 2.1. Some auxiliary lemmas, as well as a proof of Theorem 2.2, can be found in the Supplemental Material.

Proof of Theorem 2.1

As noted in the main text, our derivation of the limiting distribution of \( \hat{\beta} \) utilizes the decomposition

\[
\hat{\beta} = \hat{\beta}_i + \hat{\Xi}_N(\hat{\delta} - \delta_0),
\]

with \( \hat{\beta}_i \), \( \hat{\delta} \), and \( \hat{\Xi}_N \), respectively, equal to (26), (24), and (28) in the main text. The proof proceeds in three steps. First, we derive the limiting distribution of the infeasible estimator \( \hat{\beta}_i \); second, that of the common parameters \( \hat{\delta} \). Third, we show that \( \hat{\Xi}_N \) has a well defined probability limit. The limiting distribution of \( \hat{\beta} \) then follows from the delta method and the independence of \( \hat{\beta}_i \) and \( \hat{\delta} \).

Large Sample Properties of \( \hat{\beta}_i \)

We begin with the infeasible estimator (26), which treats \( \delta_0 \) as known. Re-centering (26) yields

\[
\hat{\beta}_i - \beta_0 = \frac{1}{N} \sum_{i=1}^{N} \mathbf{1}(|D_i| > h_N) (X_i^{-1}(Y_i - W_i \delta_0) - \beta_0).
\]

First consider the expected value of the term entering the summation in the denominator of (38):

\[
\mathbb{E}[\mathbf{1}(|D| > h)] = 1 - \mathbb{P}(|D| \leq h)
= 1 - h \int_{-1}^{1} \phi(uh) du
= 1 - 2h\phi_0 + o(h),
\]

where the second equality follows from Assumption 1.2 and the change of variables \( u = t/h \) (with Jacobian \( dt/du = h \)).

Define \( Z_{N,i} \) to be the term entering the summation in the numerator of (38):

\[
Z_{N,i} = \mathbf{1}(|D| > h) (X_i^{-1}(Y_i - W_i \delta_0) - \beta_0).
\]
Taking its expectation yields

\[
\mathbb{E}[Z_{N,i}] = \mathbb{E}\left[ \mathbf{1}(|D_i| > h) \cdot (\beta_0(X_i) - \beta_0) \right] \\
= \mathbb{E}\left[ \mathbf{1}(|D_i| \leq h) \cdot (\beta_0 - \beta_0(D_i)) \right] \\
= \int_{-h}^{h} (\beta_0 - \beta_0(t)) \phi(t) \, dt \\
= 2(\beta_0 - \beta_0^S) \phi_0 h + o(h),
\]

where \( \beta_0^S \equiv \beta_0(0) \), again using Assumption 1.2.

Turning to the variance of \( Z_{N,i} \) we use the analysis of variance (ANOVA) decomposition

\[
\text{Var}(Z_{N,i}) = \text{Var}\left( \mathbb{E}[Z_{N,i}|D_i] \right) + \mathbb{E}\left[ \text{Var}(Z_{N,i}|D_i) \right].
\]

The first term in (42) equals

\[
\text{Var}\left( \mathbb{E}[Z_{N,i}|D_i] \right) = \text{Var}(1(|D_i| > h) (\beta_0(X_i) - \beta_0)) \\
= \text{Var}(1(|D_i| > h) (\beta_0(D_i) - \beta_0)) \\
= \text{Var}(\beta_0(D_i)) + o(1).
\]

Now consider \( \text{Var}(Z_{N,i}|D_i) \); using (41) above and recalling the equality \( X^{-1} = \frac{1}{D}X^* \) when \( |D| > 0 \), we have

\[
Z_{N,i} - \mathbb{E}[Z_{N,i}|D_i] \\
= \mathbf{1}(|D_i| > h) \left\{ X_i^{-1}(Y_i - W_i\delta) - \beta_0 - (\beta_0(D_i) - \beta_0) \right\} \\
= \frac{1}{D_i} \mathbf{1}(|D_i| > h) \left\{ Y_i^* - W_i^*\delta - D_i\beta_0(D_i) \right\} \\
= \frac{1}{D_i} \mathbf{1}(|D_i| > h) X_i^*(Y_i - W_i\delta - X_i\beta_0(D_i)).
\]

Again defining

\[
U_i \equiv Y_i - W_i\delta - X_i\beta_0(X_i) \\
= Y_i - W_i\delta - X_i\beta_0(D_i) + X_i(\beta_0(X_i) - \beta_0(D_i)),
\]

it follows from iterated expectations that

\[
\text{Var}(Z_{N,i}|D_i) \\
= \frac{1}{D_i^2} \mathbf{1}(|D_i| > h_N) \\
\times \mathbb{E}\left[ X_i^*(Y_i - W_i\delta - X_i\beta_0(D_i))(Y_i - W_i\delta - X_i\beta_0(D_i))'X_i^*|D_i \right].
\]
\[
\frac{1(|D_i| > h_N)}{D_i^2} \mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i]
\]
\[
+ \frac{1(|D_i| > h_N)}{D_i^2} \mathbb{E}[(\beta(X_i) - \beta_0(D_i))(\beta(X_i) - \beta_0(D_i))'|D_i]
\]
\[
= \frac{1(|D_i| > h_N)}{D_i^2} \mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i] + 1(|D_i| > h_N) \mathbb{V}(\beta(X_i)|D_i),
\]

where \( \Sigma(X_i) \equiv \mathbb{V}(U_i|X_i) \). Averaging the first term in \( \mathbb{V}(Z_{N,i}|D_i) \) over the distribution of \( D_i \) gives

\[
\mathbb{E} \left[ \frac{1(|D_i| > h_N)}{D_i^2} \mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i] \right]
\]
\[
= \int_{-h}^{-1} \frac{1}{t^2} \mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i = t] \phi(t) \, dt
\]
\[
+ \int_{1}^{h} \frac{1}{t^2} \mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i = t] \phi(t) \, dt
\]
\[
= \frac{1}{h} \int_{-h}^{-1} \frac{1}{u^2} \mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i = uh] \phi(uh) \, du
\]
\[
+ \frac{1}{h} \int_{1}^{h} \frac{1}{u^2} \mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i = uh] \phi(uh) \, du
\]
\[
= \frac{2\mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i = 0]\phi_0}{h} + O(1)
\]
\[
= O(h^{-1}),
\]

where the third equality exploits Assumptions 1.2 and 2.3.

Averaging the second term over the distribution of \( D_i \) yields

\[
\mathbb{E}\left[1(|D_i| > h_N)\mathbb{V}(\beta(X_i)|D_i)\right] \leq \mathbb{E}\left[\mathbb{V}(\beta(X_i)|D_i)\right]
\]
\[
= \mathbb{V}(\beta(X_i))
\]
\[
= O(1).
\]

Thus, combining terms,

\[
\mathbb{E}\left[\mathbb{V}(Z_{N,i}|D_i)\right] = \frac{2\mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i = 0]\phi_0}{h} + O(1).
\]

Combining this result with the expression for \( \mathbb{V}(\mathbb{E}[Z_{N,i}|D_i]) \) derived above yields a variance term of

\[
\mathbb{V}(Z_{N,i}) = \frac{2\mathbb{E}[X_i^* \Sigma(X_i)X_i^*|D_i = 0]\phi_0}{h} + O(1) = O(h^{-1}).
\]
Together (41), (44), and the independence generated by random sampling (Assumption 2.1) imply that

\[
\mathbb{E}\left[\frac{1}{N} \sum_{i=1}^{N} Z_{N,i}\right] = o_p(1), \quad \forall \left(\frac{1}{N} \sum_{i=1}^{N} Z_{N,i}\right) = o_p\left(\frac{1}{Nh_N}\right)
\]

under the bandwidth assumption (Assumption 2.5). This implies weak consistency of \(\hat{\beta}_I\) for \(\beta_0\) (and indirectly Proposition 1.2).

To show asymptotic normality, we need to check the conditions for Lyapunov’s central limit theorem (CLT) for triangular arrays. Repeated use of the inequality \(\|x + y\|_3 \leq 8 (\|x\|_3 + \|y\|_3)\) yields

\[
\mathbb{E}[\|Z_{N,i}\|^3] = \mathbb{E}\left[\mathbf{1}(\{|D_i| > h_N\}) \left(\left\|X_i^{-1}(Y_i - W_i \delta_0) - \beta_0\right\|_3^3\right)\right]
\]

\[
= \mathbb{E}\left[\mathbf{1}(\{|D_i| > h_N\}) \left\|\frac{1}{D_i} X_i (Y_i - W_i \delta_0) - \beta_0\right\|_3^3\right] + O(1)
\]

\[
\leq 8 \mathbb{E}\left[\mathbf{1}(\{|D_i| > h_N\}) \left\|\frac{1}{D_i} X_i (Y_i - W_i \delta_0)\right\|_3^3\right] + O(1)
\]

\[
\leq 64 (1 + \|\delta_0\|^3)
\]

\[
\times \mathbb{E}\left[\mathbf{1}(\{|D_i| > h_N\}) \mathbb{E}(\|X_i Y_i\|^3 + \|X_i W_i\|^3 | D_i)\right] + O(1)
\]

\[
\leq 64 (1 + \|\delta_0\|^3) \mathbb{E}\left[\mathbf{1}(\{|D_i| > h_N\}) \frac{m_3(D_i)}{|D_i|^3}\right] + O(1),
\]

where \(m_3(D_i)\) is defined in Assumption 2.3. Choosing \(\bar{u} > h\) sufficiently small that \(m_3(u) \leq \bar{m}_3\) and \(\phi(u) \leq \bar{\phi}\) when \(|u| \leq \bar{u}\), yields

\[
\mathbb{E}[\|Z_{N,i}\|^3] \leq 64 (1 + \|\delta_0\|^3) \int_{h}^{\infty} \frac{1}{t^3} (m_3(t) \phi(t) + m_3(-t) \phi(-t)) dt + O(1)
\]

\[
\leq 128 (1 + \|\delta_0\|^3) \bar{m}_3 \bar{\phi} \int_{h_N}^{\bar{u}} \left(\frac{1}{t^3}\right) dt + O(1)
\]

\[
= O(h_N^{-2}).
\]

Using the above result, we can verify the Lyapunov condition. Let \(a_N = (\frac{N}{h_N})\).

Then

\[
\frac{1}{a_N} \sum_{i=1}^{N} \mathbb{V}(Z_{N,i}) \to 2 \mathbb{E}[X_i^* \Sigma(X_i) X_i^* | D_i = 0] \phi_0
\]
and also
\[
\left( \frac{\sum_{i=1}^{N} \mathbb{E}[\|Z_{N,t} - \mathbb{E}[Z_{N,i}]\|^3]}{(aN)^{1/2}} \right)^{1/3} \leq \left( \frac{8 \sum_{i=1}^{N} \mathbb{E}[\|Z_{N,i}\|^3]}{(aN)^{1/2}} \right)^{1/3} \leq O((Nh)^{-1/6}) = o_p(1).
\]

Application of the Liapunov CLT for triangular arrays, equation (39) above, and Slutsky’s theorem then yield the following lemma.

**Lemma A.1**: Suppose that (i) \((F_0, \delta_0, \beta_0(\cdot))\) satisfies (9), (ii) \(\Sigma(x)\) is positive definite for all \(x \in \mathbb{X}^T\), (iii) \(T = p\), and (iv) Assumptions 1.2–2.5 hold. Then \(\hat{\beta}_I \xrightarrow{p} \beta_0\) with the normal limiting distribution
\[
\sqrt{Nh} \mathcal{N}(\hat{\beta}_I - \beta_0) \xrightarrow{D} N(0, 2Y_0\phi_0)
\]
for \(Y_0 = \mathbb{E}[X_i^*\Sigma(X_i)X_i^*|D_i = 0]\).

**Large Sample Properties of \(\hat{\delta}\)**

Recall that the nonrandom coefficients \(\delta_0\) are estimated by a uniform conditional linear predictor (CLP) estimator. Recentering (24) yields

\[
\hat{\delta} - \delta_0 = \left[ \frac{1}{Nh} \sum_{i=1}^{N} 1(|D_i| \leq h)W_i^*W_i^* \right]^{-1} \times \left[ \frac{1}{Nh} \sum_{i=1}^{N} 1(|D_i| \leq h)W_i^*(D_i\beta_0(X_i) + U_i) \right],
\]

where

\[
U^* = Y^* - W^*\delta_0 - D\beta_0(X) = X^*(Y - W\delta_0 - X\beta_0(X)) = X^*U.
\]

First consider the expected value of the matrix being inverted in (46). Manipulations similar to those used to analyze \(\hat{\beta}_I\) above yield

\[
\mathbb{E}\left[ 1(|D_i| \leq h)W_i^*W_i^* \right] = \mathbb{E}\left[ 1(|D_i| \leq h)\mathbb{E}[W_i^*W_i^*|D_i] \right] = \int_{-h}^{h} \mathbb{E}[W_i^*W_i^*|D_i = t] \phi(t) dt
\]
AVERAGE PARTIAL EFFECTS IN PANEL DATA MODELS  

\[ h \int_{-1}^{1} \mathbb{E}[W_i^\prime W_i^\prime | D_i = uh] \phi(uh) \, du = 2 \mathbb{E}[W_i^\prime W_i^\prime | D_i = 0] \phi_0 h + o(h), \]

while for any fixed \( q \)-dimensional vector \( \lambda \), the variance of a quadratic form in that matrix satisfies

\[
\mathbb{V}[\sum_{i=1}^{N} 1(|D_i| \leq h) (\lambda^\prime W_i^\prime W_i^\prime \lambda)] \leq \frac{1}{Nh^2} \mathbb{E}[1(|D_i| \leq h) \mathbb{E}[W_i^\prime W_i^\prime | D_i] \| \lambda \|^4] = 2 \mathbb{E}[W_i^\prime W_i^\prime | D_i = 0] \phi_0 \| \lambda \|^4 + o\left( \frac{1}{Nh} \right) = O\left( \frac{1}{Nh} \right)
\]

under Assumptions 2.3 and 2.5 so that

\[
\frac{1}{Nh} \sum_{i=1}^{N} 1(|D_i| \leq h) W_i^\prime W_i^\prime = 2 \mathbb{E}[W_i^\prime W_i^\prime | D_i = 0] \phi_0 + o_p(1).
\]

Now redefine \( Z_{N,i} \) to equal the term entering the summation in the numerator of (46):

\[ Z_{N,i} \equiv 1(|D_i| \leq h) W_i^\prime (D_i \beta_0(X_i) + U_i^\prime). \]

Using the fact that \( \mathbb{E}[W_i^\prime U_i^\prime | D_i] = \mathbb{E}[W_i^\prime X_i^\prime \mathbb{E}[U|X] | D_i] = 0 \) yields an expected value of \( Z_{N,i} \) equal to

\[
\mathbb{E}[Z_{N,i}] = \mathbb{E}[1(|D_i| \leq h) W_i^\prime (D_i \beta_0(X_i) + U_i^\prime)] = \mathbb{E}[1(|D_i| \leq h) D_i \mathbb{E}[W_i^\prime \beta_0(X_i) | D_i]] = \int_{-h}^{h} t \mathbb{E}[W_i^\prime \beta_0(X_i) | D_i = t] \phi(t) \, dt = h \int_{-1}^{1} uh \mathbb{E}[W_i^\prime \beta_0(X_i) | D_i = uh] \phi(uh) \, du = \mathbb{E}[W_i^\prime \beta_0(X_i) | D_i = 0] \phi_0 h^2 \int_{-1}^{1} u \, du + \left. \frac{\partial \mathbb{E}[W_i^\prime \beta_0(X_i) | D_i = d]}{\partial d} \right|_{d=0} \phi_0.
\]
\[ + \mathbb{E}[W_i' \beta_0(X_i) | D_i = 0] \phi_0' \Bigg \{ \int_{-1}^{1} u^2 \, du + o(h^3) \Bigg \} h^3 = \frac{2}{3} \left\{ \frac{\partial \mathbb{E}[W_i' \beta_0(X_i) | D_i = d]}{\partial d} \bigg|_{d=0} \phi_0 \right\} + \mathbb{E}[W_i' \beta_0(X_i) | D_i = 0] \phi_0' \Bigg \} h^3 + o(h^3), \]

where we use the following Taylor approximation and Assumption 1.2 and 2.3 in deriving the second to last equality above:

\[ \mathbb{E}[W_i' \beta_0(X_i) | D_i = u h] u h \phi(u h) = 0 + \mathbb{E}[W_i' \beta_0(X_i) | D_i = 0] \phi_0 u h \]

\[ + \left\{ \frac{\partial \mathbb{E}[W_i' \beta_0(X_i) | D_i = d]}{\partial d} \bigg|_{d=0} \phi_0 \right\} + \mathbb{E}[W_i' \beta_0(X_i) | D_i = 0] \phi_0' \Bigg \} (u h)^2 + o(h^2). \]

The numerator (46) therefore equals

\[ \frac{1}{N h} \sum_{i=1}^{N} 1(|D_i| \leq h) W_i''(D_i \beta_0(X_i) + U_i) \]

\[ = \frac{2}{3} \left\{ \frac{\partial \mathbb{E}[W_i' \beta_0(X_i) | D_i = d]}{\partial d} \bigg|_{d=0} \phi_0 \right\} h^2 + o_p(h^2). \]

Using the ratio of (51) and (50) yields a bias expression for \( \tilde{\delta} - \delta_0 \) of

\[ \tilde{\delta} - \delta_0 = \frac{1}{3} \mathbb{E}[W_i' W_i' | D_i = 0]^{-1} \left\{ \frac{\partial \mathbb{E}[W_i' \beta_0(X_i) | D_i = d]}{\partial d} \bigg|_{d=0} \phi_0 \right\} h^2 + o_p(h^2). \]

This implies that we can center the asymptotic distribution of \( \sqrt{N h_N}(\tilde{\delta} - \delta_0) \) at zero by choosing \( h_N \) such that \( (N h_N)^{1/2} h_N^2 \rightarrow 0 \) (Assumption 2.5). Now consider the variance of \( Z_{N,i} \). As before, we proceed by evaluating the two terms in the variance decomposition (42) separately. The first of the two
terms evaluates to
\[
\mathbb{V}(\mathbb{E}[Z_{N,i}|D_i]) = \mathbb{V}(1(|D_i| \leq h) D_i \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i]) \\
= \mathbb{E}[1(|D_i| \leq h) D_i^2 \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i] \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i]] \\
- \mathbb{E}[1(|D_i| \leq h) D_i \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i] \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i]] \\
\times \mathbb{E}[1(|D_i| \leq h) D_i \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i]]'.
\]
Evaluating the two expectations that enter the above expressions yields
\[
\mathbb{E}[1(|D_i| \leq h) D_i \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i]] \\
= \int_{-h}^{h} t \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = t] \phi(t) \, dt \\
= h^2 \int_{-1}^{1} u \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = uh] \phi(uh) \, du \\
= o(h^2)
\]
and
\[
\mathbb{E}[1(|D_i| \leq h) D_i^2 \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i] \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i]] \\
= \int_{-h}^{h} t^2 \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = t] \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = t]' \phi(t) \, dt \\
= h \int_{-1}^{1} (uh)^2 \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = uh] \\
\times \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = uh] \phi(uh) \, du \\
= \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = 0] \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = 0]' \phi_0 h^3 \int_{-1}^{1} u^2 \, du + o(h^3) \\
= \frac{2}{3} \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = 0] \mathbb{E}[W_i^\nu \beta_0(X_i)|D_i = 0]' \phi_0 h^3 + o(h^3).
\]
We conclude that \(\mathbb{V}(\mathbb{E}[Z_{N,i}|D_i]) = o(h^3)\).

Now consider the second term in (42). The conditional variance, using the conditional moment restriction (9), is
\[
\mathbb{V}(Z_{N,i}|D_i) = 1(|D_i| \leq h) \mathbb{V}(D_i W_i^\nu \beta_0(X_i) + W_i^\nu U_i^*|D_i) \\
= 1(|D_i| \leq h) D_i^2 \mathbb{V}(W_i^\nu \beta_0(X_i)|D_i) \\
+ 1(|D_i| \leq h) \mathbb{V}(W_i^\nu U_i^*|D_i).
\]
Using an ANOVA decomposition to evaluate \( \mathbb{V}(W_i^U_i|D_i) \) gives
\[
\mathbb{V}(W_i^U_i|D_i) = \mathbb{E}[\mathbb{V}(W_i^U_i|X_i)|D_i] + \mathbb{V}(\mathbb{E}[W_i^U_i|X_i]|D_i)
\]
\[
= \mathbb{E}[W_i^U_i X^\star \Sigma(X) X^\star W_i^U_i|D_i] + 0,
\]
and hence
\[
\mathbb{E}\left[1 \left( |D_i| \leq h \right) \mathbb{E}[W_i^U_i X^\star \Sigma(X) X^\star W_i^U_i|D_i]\right]
\]
\[
= \int_{-h}^{h} \mathbb{E}[W_i^U_i X^\star \Sigma(X) X^\star W_i^U_i|D_i = t] \phi(t) \, dt
\]
\[
= h \int_{-1}^{1} \mathbb{E}[W_i^U_i X^\star \Sigma(X) X^\star W_i^U_i|D_i = uh] \phi(uh) \, du
\]
\[
= 2 \mathbb{E}[W_i^U_i X^\star \Sigma(X) X^\star W_i^U_i|D_i = 0] \phi_0 h + o(h).
\]
Similarly,
\[
\mathbb{E}\left[1 \left( |D_i| \leq h \right) D_i^2 \mathbb{V}(W_i^U_i \beta_0(X_i)|D_i)\right]
\]
\[
= \int_{-h}^{h} t^2 \mathbb{V}(W_i^U_i \beta_0(X_i)|D_i = t) \phi(t) \, dt
\]
\[
= h \int_{-1}^{1} (uh)^2 \mathbb{V}(W_i^U_i \beta_0(X_i)|D_i = uh) \phi(uh) \, du
\]
\[
= \mathbb{V}(W_i^U_i \beta_0(X_i)|D_i = 0) \phi_0 h^3 \int_{-1}^{1} u^2 \, du + o(h^3)
\]
\[
= \frac{2}{3} \mathbb{V}(W_i^U_i \beta_0(X_i)|D_i = 0) \phi_0 h^3 + o(h^3).
\]
Collecting terms, we conclude that
\[
(53) \quad \mathbb{V}(Z_{N,i}) = 2 \mathbb{E}[W_i^U_i X^\star \Sigma(X) X^\star W_i^U_i|D_i = 0] \phi_0 h + o(h).
\]
Applying Liapunov's central limit theorem for triangular arrays, we have
\[
\frac{1}{\sqrt{Nh_N}} \sum_{i=1}^{N} Z_{N,i} \overset{D}{\to} \mathcal{N}(0, 2 \mathbb{E}[W_i^U_i X^\star \Sigma(X) X^\star W_i^U_i|D_i = 0] \phi_0).
\]
Slutsky's theorem and (50) above then give the following lemma.

**Lemma A.2:** Suppose that (i) \((F_0, \delta_0, \beta_0(\cdot))\) satisfies (9), (ii) \(\Sigma(x)\) is positive definite for all \(x \in \mathbb{K}^T\), (iii) \(T = p\), and (iv) Assumptions 1.2–2.5 hold. Then
AVERAGE PARTIAL EFFECTS IN PANEL DATA MODELS 2149

\[ \hat{\delta} \xrightarrow{D} \delta_0 \] with the normal limiting distribution

\[
\sqrt{N h_N (\hat{\delta} - \delta_0)} \xrightarrow{D} N\left(0, \frac{\Lambda_0}{2\phi_0}\right),
\]

where

\[
\Lambda_0 = \mathbb{E}\left[ W_i^\prime W_i | D_i = 0 \right]^{-1} \times \mathbb{E}\left[ W_i^\prime X_i \Sigma(X) X_i^\prime W_i | D_i = 0 \right] \mathbb{E}\left[ W_i^\prime W_i | D_i = 0 \right]^{-1}.
\]

**Large Sample Properties of \( \hat{\beta} \)**

The following lemma characterizes the probability limit of \( \hat{\Xi}_N \).

**Lemma A.3:** If \((F_0, \delta_0, \beta_0(\cdot))\) satisfies (9) and Assumptions 1.2–2.5 hold, we have \( \hat{\Xi}_N \xrightarrow{D} \Xi_0 \), where

\[
\Xi_0 = \lim_{N \to \infty} \mathbb{E}\left[ 1(|D_i| > h_N) X_i^{-1} W_i \right] \equiv \lim_{N \to \infty} \Xi_N.
\]

See the Supplemental Material for the proof.

Lemmas A.1, A.2, and A.3 as well as the decomposition (37) then give Theorem 2.1.

**MSE-Optimal Bandwidth Sequence**

The MSE-optimal bandwidth sequence given in equation (29) of the main text can be derived as follows. Let \( a \) be a \( p \times 1 \) vector of constants. Using (41), (52), and Lemma A.3 yields a leading asymptotic bias term for \( a' \beta_0 \) of \( 2a' (\beta_0 - \beta_0^S) \phi_0 h \). Using the asymptotic variance expression given in the statement of Theorem 2.1, we get an asymptotic MSE for \( a' \hat{\beta} \) of

\[
4a' (\beta_0 - \beta_0^S)(\beta_0 - \beta_0^S)' a \phi_0^2 h^2 + \frac{a' \left( 2Y_0 \phi_0 + \Xi_0 \Lambda_0 \Xi_0' \right) a}{Nh}.
\]

Minimizing this object with respect to \( h \) gives the result in the main text.
