

The Long Run Impact of Bombing Vietnam[♦]

This draft: December 2007
First draft: January 2005

Abstract: We investigate the impact of U.S. bombing on later economic development in Vietnam. The Vietnam War featured the most intense bombing campaign in military history and had massive humanitarian costs. We use a unique U.S. military dataset containing bombing intensity at the district level (N=584). We compare the heavily bombed districts to other districts controlling for baseline demographic characteristics and district geographic factors, and use an instrumental variable approach exploiting distance to the 17th parallel demilitarized zone. U.S. bombing does not have a robust negative impact on poverty rates, consumption levels, infrastructure, literacy or population density through 2002. This finding indicates that local recovery from war damage can be very rapid under certain conditions.

♦ We are grateful to Vietnam Veterans of America Foundation (VVAF), the Defense Security Cooperation Agency (DSCA), and the Technology Center for Bomb and Mine Disposal, Vietnam Ministry of Defense (BOMICO) for providing access to the U.S. military data, and in particular to Major Patrick Keane, Benjamin Reich, Michael Sheinkman, Bill Shaw, and Tom Smith. Pamela Jakiela, Melissa Knox, Khuyen Nguyen, Rachel Polimeni, Monika Shah and especially Paul Cathcart have provided splendid research assistance. We are also grateful to Fred Brown, Jim Fearon, Raquel Fernandez, Scott Gartner, Steve Helfand, Chang-Tai Hsieh, Chad Jones, Dean Karlan, David Laitin, Robert Powell, Adam Przeworski, Martin Ravallion, Debraj Ray, John Strauss and to numerous seminar participants at Harvard / MIT, ECARES-ULB, the 2005 ASSA Meetings, U.C. Riverside, U.C. Berkeley, University of British Columbia, the Pacific Development Conference, University of Michigan, Center for Global Development, Stanford University, the MacArthur Inequality Network, BREAD-CEPR Conference, Economic History Association Meetings, NYU, Cornell, and Yale for useful comments.

1. Introduction

The horrors inflicted by war are clear to all, and so are its disruptive effects for people's lives. Indeed, war displaces population, destroys capital and infrastructure, disrupts schooling, and can produce negative environmental impacts, damage the social fabric, endanger civil liberties, and create health and famine crises. Any of these effects could be argued to have impacts on later economic growth and development, and their combined effects even more. Jean Drèze for one forcefully expresses the view that “[w]ars or rather militarism is the major obstacle to development in the contemporary world” (Drèze 2000: 1171).

Yet the net long run effects of war are unclear a priori. In particular, standard neoclassical growth theory yields ambiguous predictions regarding the effect of war on long-run economic performance. To the extent that the main impact of war is the destruction of existing physical capital and temporary reduction of human capital accumulation, neoclassical models predict rapid postwar catch-up growth as the economy converges back to its steady state growth rate, resulting in no long-run impact. At the same time, war may also profoundly affect the quality of institutions, technology, and social outcomes. These institutional effects of war may in turn have negative or positive impacts on long-run economic performance. For instance, it is often argued that military research and development leads to faster technological progress, which may offset war damage. Wars may also promote state formation and nation building as was the case in Europe (Tilly 1975), and may induce social progress via greater popular participation (Keyssar 2000) or break the power of entrenched groups that block growth-promoting policies (Olson 1982).

There is now a large literature, both theoretical and empirical, on the causes of armed conflict (see e.g. Fearon, 1995, Fearon and Laitin, 2003, Collier and Hoeffler, 1998 and 2004, Powell, 2004) but the long run economic impacts of war remain largely unexplored empirically, and this is so for several reasons. One important issue is the difficulty of convincingly identifying war impacts on economic growth in the presence of dual causality between violence and economic conditions, and

possible omitted variable biases (Miguel et al 2004). But a perhaps even more fundamental constraint for empirical work is the lack of data on war damage and economic conditions in conflict and post-conflict societies. We exploit a data-rich historical episode to estimate bombing impacts on long-run economic performance, the U.S. bombing of Vietnam (what Vietnamese call “the American War”).

The Indochina War, centered in Vietnam, was the most intense episode of aerial bombing in human history (Clodfelter 1995):

“The United States Air Force dropped in Indochina, from 1964 to August 15, 1973, a total of 6,162,000 tons of bombs and other ordnance. U.S. Navy and Marine Corps aircraft expended another 1,500,000 tons in Southeast Asia. This tonnage far exceeded that expended in World War II and in the Korean War. The U.S. Air Force consumed 2,150,000 tons of munitions in World War II – 1,613,000 tons in the European Theater and 537,000 tons in the Pacific Theater – and 454,000 tons in the Korean War.”

Vietnam War bombing thus represented at least three times as much (by weight) as both European and Pacific theater World War II bombing combined, and about fifteen times total tonnage in the Korean War. Given the prewar Vietnamese population of 32 million, U.S. bombing translates into hundreds of kilograms of explosives per capita. For another comparison, the atomic bombs dropped at Hiroshima and Nagasaki had the power of roughly 15,000 and 20,000 tons of TNT, respectively (Grolier 1995). Since general purpose bombs – by far the most common type of bomb used in Vietnam – are approximately 50% explosive material by weight, each atomic bomb translates into roughly 30,000 to 40,000 tons of such munitions. Measured this way, U.S. bombing in Indochina represents 100 times the combined impact of the Hiroshima and Nagasaki atomic bombs.

This study employs an unusual United States military district-level dataset on bombs, missiles, rockets and other ordnance dropped in Vietnam. The U.S. bombing of Vietnam was largely concentrated in a subset of regions: roughly 70% of total ordnance was dropped in only 10% of our 584 sample districts. Figure 1 highlights the 10% most heavily bombed districts.

The heaviest bombing took place in Quang Tri province in the central region of the country near the 17th parallel, the former border between North Vietnam and South Vietnam. Quang Tri

province was basically bombed flat during the war, with most of its capital and infrastructure destroyed: only 11 of 3,500 Quang Tri villages were left unbombed by the end of the war (Project RENEW Report 2004: 3). Provinces immediately north and south of Quang Tri also received heavy U.S. bombing, although less than Quang Tri itself. Coastal regions of North Vietnam and some districts of Hanoi were heavily bombed, as was the region near Saigon adjacent to Cambodia. This region was the site of frequent incursions by North Vietnam Army and NLF/Vietcong troops into South Vietnam through the so-called Ho Chi Minh Trail that ran through Laos and Cambodia.

There are many reasons U.S. bombing could have long-run impacts on Vietnamese economic development, and we focus on three in particular. First, the destruction of local infrastructure may have inhibited commerce and changed later investment patterns. For instance, U.S. bombing during the Rolling Thunder campaign of the late 1960s “destroyed 65 percent of the North's oil storage capacity, 59 percent of its power plants, 55 percent of its major bridges” (Clodfelter 1995: 134).¹ Second, U.S. bombing displaced population and this could potentially have reduced local economic activity if many individuals never returned. Third, population displacement and the destruction of physical infrastructure – including classrooms – disrupted schooling for millions. In terms of other possible factors, we do not have complete information on unexploded ordnance (UXO), landmines or Agent Orange use, and unfortunately cannot focus on these in the main empirical analysis (however, there is obviously a strong correlation between bombing and later UXO density).²

This paper exploits the extensive variation in U.S. bombing intensity across 584 Vietnamese districts to estimate long-run local impacts of the war. We find no robust adverse impacts of U.S. bombing on poverty rates, consumption levels, electricity infrastructure, literacy, or population

¹ See Tilford (1991: 155) for further details on the extent of U.S. bombing damage.

² UXOs as well as landmines can impair the use of agricultural land and are expensive to find and remove. While UXOs and landmines can seriously hurt farming families when an income earner is victimized, UXO and landmine injury rates in Vietnam during the 1980s and 1990s declined rapidly relative to the immediate postwar years (Project RENEW report 2004: 16-18). The chemical agents used by the U.S. could also generate long term damage to population health and land. The best known, Agent Orange, is a defoliant containing dioxins, and as late as 2001 traces of dioxins specific to Agent Orange were still found in human blood in some areas. Deforestation itself could also negatively affect the environment and agriculture by increasing soil instability and affecting wildlife.

density through 2002. These results are consistent across a variety of specifications and samples. There is a moderate negative effect of U.S. bombing on consumption levels in 1992/1993, but also evidence for a large positive effect on consumption growth between 1992/1993 and 2002, suggesting that any negative war impacts on local living standards dissipated over time as a result of rapid catch-up growth. While the precise mechanisms underlying these main results remain elusive, there is some evidence that extra state investment in heavily bombed regions played a role in the postwar recovery. To be absolutely clear, the humanitarian costs of the Vietnam War itself – which led to millions of civilian deaths by all accounts – were massive even if there are no long-run impacts on local economic performance.

The key issue for inference is the non-random nature of U.S. bombing patterns. If regions with unobservably better economic growth prospects were more (or less) likely to be heavily bombed, this could bias estimated impacts. Understanding the sources of variation in U.S. bombing is thus critical. In this regard, the estimation strategy benefits from at least two factors. First, the most heavily bombed areas were those located near the 17th parallel north latitude, the border between North and South Vietnam during the war. This arbitrary border, set by the 1954 Geneva Accords that ended French colonialism in Indochina, became a locus for heavy fighting during the war, and its placement at 17 degrees, rather than 16 or 18 degrees, can be viewed as a natural experiment. The border was not drawn by Vietnamese, but was instead the outcome of fierce negotiations among the United States and Soviet Union in the context of the Cold War. The U.S. sought to push the border farther north, the Soviet Union south. We use the north-south distance from a district to the 17th parallel as an instrumental variable for bombing intensity in our preferred empirical specification, exploiting this source of variation.

The second main concentration of heavy U.S. bombing lies in areas where the Ho Chi Minh Trail entered South Vietnam. While not as clearly exogenous as the North Vietnam-South Vietnam border, the outlets of the Ho Chi Minh Trail into South Vietnam reflected, to a large extent,

geographical conditions along the South Vietnam-Cambodia border rather than local socioeconomic conditions within Vietnam. At its main southern outlet, there was less mountainous terrain than is the case farther north along the border, facilitating troop movements into the Mekong Delta flatlands. All the analysis includes baseline 1960-61 population density and geographic and climatic characteristics as regression controls, as well as province fixed effects in some specifications.

It is important to note an important limitation up front: while this econometric strategy provides estimates of differences across districts, the approach is unable to capture aggregate nationwide effects of the war on Vietnamese development. The counterfactual – Vietnamese economic performance in the absence of the “American War” – cannot be observed or estimated. This is potentially important to the extent that the war led to major institutional and social changes, or if the cross-region spillovers of the war within Vietnam were large. Still the rapid rate of economic growth in Vietnam since the early 1990s – at 6% on average between 1993 and 2003 (World Bank 2004) – suggests that any nation-wide war impacts on economic growth rates were not persistently negative. The within-country empirical approach also has merits. Exploiting the common data sources and postwar institutions and policies across Vietnamese regions allows us to pinpoint local economic impacts of bombing more precisely than is possible in cross-country analyses, where controlling for national trends and institutions is more problematic.

In related work, Davis and Weinstein (2002) show that the U.S. bombing of Japanese cities in World War II had no long run impact on the population of those cities relative to prewar levels, and Brakman et al. (2004) find a similar result for postwar Germany. Organski and Kugler (1977, 1980) find that the economic effects of the two world wars tended to dissipate after only 15-20 years, for both capitalist and socialist economies, after which there was a return to prewar growth trends. Przeworski et al. (2000) similarly find rapid postwar recovery in a cross-country analysis.

We view our results as complementary to these earlier studies. We are able to measure the long run impact of bombing on a larger set of outcomes than other studies, which either only focus

on population effects or on aggregate growth. By examining the effect of bombing on (i) variables that are central to understanding economic performance – physical capital, human capital and population – and on (ii) other variables that relate directly to human welfare, including poverty rates and consumption, we paint a more complete picture of long run bombing impacts.

In terms of other differences with existing studies, note that Vietnam during the 1960s and 1970s was much poorer than either Japan or Germany and was an overwhelmingly rural country. The urban agglomeration effects emphasized by some theories thus likely played a less important role in Vietnamese recovery. Another major difference between postwar Vietnam and Japan is that the former was a centrally planned economy until it launched market reforms in the late 1980s while the latter was always a market economy. This raises the question of what general lessons we can learn from these empirical studies, since other countries with different institutions might have reacted differently. It is important to emphasize that institutions are often quite country specific. Japan has unique capitalist institutions that differ from the U.S., for example, and the Vietnamese form of socialism was quite different from East German central planning. In our view it is only through the accumulation of evidence across many settings that researchers can create a convincing picture of war's long-run economic effects. Nevertheless, our results have particular salience for understanding the capacity of a less developed country to recover from an extremely intense bombing experience.

2. War and Growth Theory

It is useful to recall results from the standard Ramsey growth model to provide perspectives on war's possible economic impacts. If war leads to the partial destruction of the physical capital stock but the production function remains unchanged, there will be a temporary increase in capital accumulation until the steady state is again attained. In other words, war has no long run effects on the economy but leads to a transitory increase in investment and consumption growth relative to a situation without war. If war leads to a loss of the capital stock in some areas but not others, the former will

experience temporarily higher growth. If capital is mobile, capital will also flow to the war-damaged areas so as to equalize marginal returns across regions.

Postwar recovery patterns are qualitatively similar for human capital (see Barro and Sala-i-Martin 2003 for a fuller treatment of two-sector growth models). A reduction in human capital in a war torn region will also result in more rapid postwar accumulation of human capital there, though again there will be no change in the steady state provided that other model parameters are unchanged.

The effects of a loss of capital stock in a growth model with vintage capital are somewhat different. To the extent that postwar investment consists of more recent and better quality capital, economic performance could eventually exceed that of the prewar economy and thus regions that suffered more from the war might eventually overtake regions that suffered less. Gilchrist and Williams (2004) indeed argue that a vintage capital growth model is more consistent with macroeconomic recovery patterns in postwar Japan and Germany than the standard neoclassical model. Our main empirical findings appear to be consistent with both the neoclassical and vintage capital views, and we do not attempt to decisively distinguish between these two models below since for us the key issue is to determine whether or not long-run local economic impacts can be detected.

Another reason why the steady state of the economy could be affected by war is the possibility of falling into a poverty trap (Azariadis and Drazen 1990, World Bank 2003). Given its low initial income and the extensive U.S. bombing, if a war induced “poverty trap” would ever be possible Vietnam would be a good candidate. But empirically we will find no evidence for local poverty traps in Vietnam.

Beyond the loss of physical and human capital, war could also lead to institutional changes that would affect the aggregate production function, by modifying its scale parameter. Theory does not provide an unambiguous prediction as to the effect of war on institutions and technology. Deterioration in institutions could thus lead to a new steady state characterized by a lower long run

level of both capital and consumption, while by symmetry, positive institutional changes brought about by war could boost steady state capital and consumption postwar.

The possibility of cross-regional spillovers is also important to the extent that economic conditions in one region affect growth elsewhere. Central government taxation and transfers may also benefit some regions more than others. In the empirical analysis below, we explore the possibility of cross-district spillovers by examining relationships at different levels of aggregation (namely, at both provincial and district levels), and also examine postwar state investment patterns to establish whether the areas most affected by U.S. bombing benefited from additional investment.

3. The Data

We use a database assembled by the Defense Security Cooperation Agency (DSCA) housed at the United States National Archives in Record Group 218, called “Records of the U.S. Joint Chiefs of Staff”.³ The database contains information on all ordnance dropped from U.S. and allied airplanes and helicopters in Vietnam between 1965 and 1975, as well as artillery fired from naval ships.⁴ To our knowledge, these files embody the most complete, comprehensive and reliable summary available of U.S. and allied ordnance expended during the Vietnam War. Some of the original tape archives were reportedly damaged so up to several months of data may be missing, but unfortunately we are unable to determine the precise extent of any missing data. The data were originally recorded in aircraft mission logs and then reported to Pacific Command and the Joint Chiefs of Staff. They were declassified and provided to the Vietnamese government following the war. The Data Appendix discusses data sources in greater detail.

³ We obtained the data from the Vietnam Veterans of America Foundation (VVAFF) with authorization from DSCA and the Vietnam Ministry of Defense Technology Center for Bomb and Mine Disposal.

⁴ In particular, data come from the 1965-70 Combat Activities-Air (CACTA), the 1970-1975 South East Asia (SEADAB), and Combat Naval Gunfire (CONGA) databases.

The raw data include the bombing location, a summary bomb damage assessment (which we unfortunately do not have access to, since this would be useful in the analysis), and the quantity of ordnance by category and type. Categories include general purpose bombs, cluster bombs, chemicals, incendiary, rockets, missiles, projectiles, ammunition, mines and flares. Ordnance is measured in units rather than by weight. Since the source of the data is the U.S. Air Force and Navy, we miss anti-personnel landmines that were placed by Army ground forces, which probably accounts for a large share of U.S. landmines, and the landmine data are thus less reliable than the other data. The raw data were then geo-coded by the VVAF using Vietnam district boundaries employed in the 1999 Population and Housing Census to yield the dataset we use. (An examples of the raw data is presented in Appendix Figure 1.)

General purpose bombs are by far the most common ordnance category (Table 1). The Mark 82 and Mark 36 Destructor general purpose bombs typically weighed between 500 to 750 pounds. Bombing intensity was high, with an average of 32.3 bombs, missiles, and rockets per km² nationwide through the war, and there is extensive variation across districts for all ordnance categories. The distribution of bombing was skewed, with 10% of districts receiving nearly 70% of all bombs, missiles and rockets⁵, and some districts receiving over 500 bombs per km², while many districts were not bombed at all. The most intense attacks took place near the 17th parallel that formed the border between North and South Vietnam during the war. Note that the poor northwestern region was hardly bombed at all, in part because of the Johnson administration's reluctance to antagonize China by bombing near its borders (Tilford 1991: 153).

There is a positive and statistically significant correlation across all ordnance categories (Table 1). In the analysis below, we mostly employ total intensity of bombs, missiles, and rockets per km², but given the substantial correlation with other ordnance categories (e.g. ammunition), this is

⁵ Quang Tri district in Quang Tri province, which is only 6 km² in size, received over 3000 bombs per km², the highest by far. We exclude this outlier in the analysis while still using data from the rest of Quang Tri province.

also a good proxy for overall war activity. Unfortunately, we do not have comparable data for North Vietnam Army or NLF/Vietcong ordnance nor do we have ordnance damage measures. Although we do not have disaggregated Agent Orange exposure data, the broad regional patterns of exposure from the maps in Stellman et al (2003) correspond closely with those in our data base.

We obtained 1960-61 provincial population density from both South Vietnam and North Vietnam government sources (see the Data Appendix) and use those data as baseline controls in the regressions (Table 2). A variety of district geographic and climatic characteristics – including proportion of land at high altitude, average district temperature and precipitation, location in former South Vietnam, and the proportion of land in 18 different soil type categories – are also included as explanatory variables to partially control for agricultural productivity and factors potentially affecting military strategy (e.g., altitude). The soil controls are excluded from the province level analysis due to limited degrees of freedom, as there are only 55 provinces in the province sample.

We focus on several economic outcomes. Poverty rate estimates are from Minot et al. (2003), who use the Elbers et al (2003) local regression method. This approach matches up 1999 Population and Housing Census data – which has excellent geographic coverage but limited household characteristics – with detailed 1997/8 Vietnam Living Standards Survey (VLSS) household data. Log-linear regressions of real cost-of-living-adjusted per capita consumption expenditures on the 17 household characteristics found in both the census and VLSS are then carried out, and the results used to compute predicted household consumption (details are in the Data Appendix). The poverty rate is the proportion of population estimated to be living on less than the official 1999 national poverty line of 1,789,871 Dong, and approximately 41% of the national population met this criterion (Table 2). The 1999 census also provides information on household access to electricity (71% of households nationwide) and literacy (88% of respondents), our proxies for past physical and human capital investments, respectively.

We obtained per capita consumption expenditure data from both the 1992/3 and 2002 VLSS waves for a sample of households in a subset of 166 districts. We focus on province level averages with the VLSS, since the data was designed to be representative at this level of aggregation. The VLSS also contains useful retrospective information on migration that we use below.

Finally, Vietnamese Statistical Yearbooks provide a consistent series on province population for 1985 to 2000, and some information on central government investment flows for 1985. Unfortunately, more detailed economic data is lacking for the 1970s and 1980s, a period which constitutes a sort of statistical black hole. Recall that in the aftermath of the “American War”, Vietnam also fought a border war with China and occupied Cambodia to end Khmer Rouge rule, and data collection was a low priority for the regime while the country remained on a war footing.

4. Determinants of U.S. Bombing Intensity

Before presenting the econometric analysis, we discuss the existing literature on U.S. bombing strategy during the Vietnam War. A distinction is often made between the nature of bombing in North Vietnam versus South Vietnam. U.S. bombing in North Vietnam is largely considered *strategic bombing*, targeting transportation capabilities (e.g., airfields, railroads, bridges, ports, roads), as well as military barracks, industrial plants, and storage depots (Clodfelter 1995: 134). The selection of targets in North Vietnam was directly supervised by Washington officials on a weekly basis during the Johnson administration’s “Rolling Thunder” air campaign (Littauer et al., 1972: 37), and the number of approved targets regularly fell below the requests of the military, with the bombing of Hanoi, Haiphong and areas near the Chinese border categorically ruled out. A far broader set of targets in North Vietnam was approved under the Nixon administration’s “Linebacker” campaign, including the major population centers.

Bombing in South Vietnam, and in parts of North Vietnam near the border, in contrast, was typically *interdiction bombing* or tactical air support, which aimed to disrupt enemy troop

movements and support U.S. ground troop operations, rather than explicitly to destroy infrastructure (Littauer et al 1972: 55; Schlight 1988: 292). Below we present empirical results broken down by the former North and South Vietnam in some cases, in addition to full sample estimates, to investigate differential impacts. Some existing research suggests there was no robust correlation between local population density and U.S. bombing intensity (Nalty 2000: 83) but other authors claim poorer areas were actually more likely to be hit: “[i]n the remoter, sparsely populated regions often used by the NLF/NVA [North Vietnam Army] for staging, regroupment, and infiltration, area saturation bombing is common” (Littauer et al 1972: 10-11).

Turning to the statistical analysis, the north-south distance from the 17th parallel is a strong predictor of bombing intensity and is statistically significant in the province level analysis (Table 3, regression 1), district level analysis (regression 2), and a specification that excludes Quang Tri province, the most heavily bombed province (regression 3). The main district level specification in regression 2 serves as the first stage for the subsequent IV-2SLS analysis. Note that the instrument is highly statistically significant with a t-statistic near three in that case. In all specifications disturbance terms are allowed to be correlated (“clustered”) for districts within the same province, in case there are correlated local geographic, socioeconomic or political factors.⁶

A remaining econometric concern is whether the instrumental variable violates the exclusion restriction, in the sense that distance from the 17th parallel has an independent impact on postwar outcomes beyond any effects working through bombing intensity (conditional on the control variables). One possible concern is that the IV is correlated with distance to one of Vietnam’s two major cities, Hanoi and Ho Chi Minh City. If remoteness from these two booming metropolitan areas is associated with lower incomes during the postwar period, as seems likely, this would generate a negative correlation between distance to the 17th parallel and poverty in 1999. However, despite any

⁶ The use of general spatially correlated disturbance terms, as in Conley (1999), leads to standard errors very similar to those produced by clustering districts by province throughout (results not shown).

such possible bias, below we find no significant relationship between bombing and later poverty in the IV specification. In other words, despite the fact that districts near the 17th parallel had the double misfortune of being both heavily bombed and far from major national markets, they are currently no poorer than other regions (conditional on baseline characteristics).

None of the other explanatory variables is significantly related to U.S. bombing intensity in a consistent way across the three specifications in Table 3, including the indicator for former South Vietnam, altitude measures, climatic conditions and latitude. The one partial exception is the prewar 1960-61 province population density measure, which is negative and statistically significant across the two district level specifications, suggesting that more rural areas were somewhat more likely to be bombed, echoing some of the existing historical literature. However, note that this result does not hold in the province level analysis in regression 1. Thus overall, with the exception of distance to the 17th parallel (the instrumental variable), there are no consistent correlations between observables and bombing intensity, partially alleviating omitted variable bias concerns.

5. The Long-run Impact of Bombing Vietnam

5.1 Impacts on Poverty and Consumption Expenditures

We consider local bombing impacts at both the province and district levels. There are a number of reasons to consider outcomes at different levels of aggregation. First, U.S. bombing of one district could generate negative externalities for nearby districts. Provincial level regressions are one way to partially capture these externalities, although this specification still misses even broader cross-province externalities. Second, the main baseline 1960-61 population density control is at the province level, and thus when population density is the dependent variable at least (in Section 5.3 below), the analysis utilizes a true panel design. Finally, the province results serve as a robustness check for the district level analysis.

Total U.S. bombing intensity is negatively and marginally statistically significantly related to the 1999 poverty rate at both the province level (Table 4, regression 1) and the district level (regression 2) in OLS regressions. The district level relationship between bombing intensity and poverty is presented graphically in Figure 2. The main empirical results are similar if we consider only the intensity of general purpose bombs, the major ordnance category, or if we consider a log transformation of total bombing intensity (not shown). In terms of other factors, areas that had higher population density in 1960-61 have significantly less poverty in 1999 as expected, as does South Vietnam as a whole on average, while high altitude areas have considerably more poverty (regressions 1 and 2). Climatic factors and latitude, in contrast, are not robustly associated with poverty, although high precipitation areas have significantly more poverty in some specifications.

The district level effect remains negative and is even more statistically significant in specifications that include province fixed effects (Table 4, regression 3) and exclude Quang Tri (regression 4). Overall, the OLS specifications provide suggestive evidence that U.S. bombing moderately reduced later poverty, but estimates are only marginally significant and not particularly robust. This negative relationship may in part reflect the fact that some of the poorest provinces in Vietnam, those in the northwest, were rarely bombed by the U.S. due to their proximity to China, potentially generating a spurious correlation. More generally, some other unobserved source of socioeconomic variation could be driving both observed bombing patterns and later poverty.

We thus next turn to estimates that rely on the placement of the North Vietnam-South Vietnam border at the 17th parallel as exogenous variation in bombing intensity. In the reduced form specification (Table 4, regression 5), the north-south distance from the 17th parallel is negative but not statistically significantly related to 1999 poverty, conditional on all other geographic factors. Using this distance as an instrumental variable for bombing intensity in our preferred specification, the relationship between bombing intensity is positive but not statistically significant (regression 6): the coefficient estimate on total bombing intensity is 0.00026 (standard error 0.00042).

To get an idea of the magnitude of this estimated bombing impact on later poverty, first consider the effect of a change from zero bombing up to the average bombing intensity of 32.3 bombs, missiles, and rockets per km². The average effect in this sense is $(32.3) \times (0.00026) = 0.008$. This is a very small average effect, an increase in the poverty rate by less than one percentage point and it is not statistically significant. In terms of how precise this estimate is, the 95% confidence interval ranges from $0.00026 - 2 \times 0.00042 = -0.00058$, up to $0.00026 + 2 \times 0.00042 = 0.0011$. Thus again considering the effect of going from zero bombing up to the average intensity of 32.3, the 95% confidence band of estimates is $(32.3) \times (-0.00058) = -0.019$ to $(32.3) \times (0.0011) = 0.035$. In other words, plausible average effects range from a 1.9 percentage point reduction in poverty up to a 3.5 percentage point increase in poverty on a base poverty rate of 41%, a reasonably tight range. The analogous exercise using the OLS estimate (Table 4, regression 2) yields a point estimate of $(32.2) \times (-0.00040) = -0.013$, a 1.3 percentage point reduction in poverty (going from zero bombing up to average bombing intensity), and a 95% confidence interval from a -2.7 percentage point decrease in poverty up to a +0.1 percentage point increase, again a narrow range of estimates around zero.

The effect of bombing on poverty is negative and statistically significant in former North Vietnam (Table 5, regression 1) but not in former South Vietnam (regression 2). The explanation for this North-South difference remains elusive. It might reflect a postwar government bias towards assisting heavily bombed areas in the North but the different nature of bombing across the two regions might also be part of the story. Bombing effects are not statistically significant in initially rural areas (districts with baseline 1960-1 population density less than 200 per km², regression 3) but are statistically significant and negative in urban areas (regression 4). There is some evidence for a nonlinear effect of bombing intensity on later poverty rates: the linear bombing term remains negative and statistically significant while the squared term is positive and significant (regression 5). This pattern appears to in part reflect the high poverty rates in Quang Tri province, the most heavily bombed province in the country and suggests that war impacts can be persistent for extremely intense

bombing like that in Quang Tri, although that is speculative. Point estimates are however not statistically significant using an alternative nonlinear measure of heavy bombing (regression 6).

Using the more detailed VLSS household consumption expenditure data, average consumption per capita in 2002 is not robustly associated with bombing intensity across the full sample (Table 6, Panel A, regression 1), or in a specification that excludes Quang Tri province (regression 2), or in a specification that includes the north-south distance to the 17th parallel as the main explanatory variable (regression 3). In contrast, all three specifications indicate that more heavily bombed provinces were somewhat poorer in 1992/93 (Table 6, Panel B), although effects are not significant at traditional confidence levels.

Taking the growth rate of per capita consumption expenditures as the dependent variable, we find that provinces that experienced more intense U.S. bombing had significantly faster growth between 1992/93 and 2002 (Table 6, Panel C), and this effect is statistically significant at over 95% confidence. The coefficient estimate from the full sample (regression 1) implies that going from zero to average U.S. bombing intensity is associated with $(32.3) \times (0.0030)$ or 10 percentage points faster consumption expenditure growth during that ten year period, a substantial difference that works out to be roughly one percentage point faster growth per year on average.

These patterns suggest that more heavily bombed areas were somewhat poorer than other areas soon after the war but they later caught up during the 1990s economic boom, in line with the neoclassical growth model's prediction of especially rapid consumption growth along the transition path to steady state. Unfortunately, due to data limitations we cannot trace out consumption growth patterns in the 1970s and 1980s, and so cannot estimate the extent of poverty immediately postwar. Nevertheless, by 2002, nearly thirty years after U.S. troops pulled out of Vietnam, living standards in the provinces that bore the brunt of the U.S. assault are largely indistinguishable from other areas.⁷

⁷ We examined attained adult height from the VLSS as a measure of living standards for cohorts born before and during the war to gauge the extent to which living standards fell in heavily bombed areas. We find that average

5.2 Impacts on Infrastructure and Human Capital

There is a positive relationship between U.S. bombing intensity and 1999 access to electricity across the standard set of province and district specifications (Table 7, panel A), and coefficient estimates are statistically significant at 95% confidence in six of seven specifications. The relationship is weaker when province fixed effects are included as controls (regression 3), but the point estimate on U.S. bombing remains positive and marginally statistically significant even in that case. Note the negative and significant coefficient estimate on north-south distance to the 17th parallel, suggesting particularly intensive power sector investments near the former border.

Taken together these estimates provide some evidence of technological “leapfrogging” in the heavily bombed regions, consistent with either a vintage capital growth model, or investments in the heavily bombed regions that far exceeded war damage. Speculatively, this may have been a political reward for regions that actively resisted the U.S. during the war. However, given the limited data available immediately postwar, we have little hope of determining the relative contributions of these two explanations. Infrastructure investment decisions in Vietnam in the 1970s, 1980s and 1990s likely reflected a combination of central government redistributive goals as well as potential private returns, especially in the aftermath of the economic reforms, and it is difficult to disentangle these motives in the absence of detailed micro-level public and private investment data, which do not exist to our knowledge. International donors, non-governmental organizations (NGOs) and even the U.S. government (following the 1995 normalization of relations with Vietnam) also played important roles in reconstruction, further complicating interpretation.

height for the 1961-70 and 1971-80 birth cohorts is significantly lower in more heavily bombed regions. However, it is also somewhat lower for earlier cohorts (born pre-1961) in those same areas. The largest coefficient estimate on U.S. bombing intensity (for the 1961-70 cohort) is -0.0165, implying an average reduction of 0.5 cm when going from zero to average U.S. bombing intensity – not a large effect. The relatively small sample sizes in the VLSS, especially when the data are broken down by year of birth, gender, and province cells, and the possibility that children across a range of ages could experience some growth stunting, prevent us from drawing strong conclusions. The possibility of differential child and infant mortality as a result of the war could also generate selection effects that would further complicate the analysis.

Another factor in the neoclassical growth model is human capital. There are no statistically significant negative impacts of bombing on either province or district literacy rates in 1999, a proxy for human capital investment (Table 7, Panel B, regressions 1-6), and similarly weak results hold for other 1990s human capital measures from the VLSS database as well as for 1985 school enrollment data from government yearbooks (results not shown).

There is thus no evidence that more heavily bombed districts have either less physical infrastructure or human capital stocks 25 years after the end of the war, consistent with the rapid postwar recovery in consumption levels documented above. But this is not to say that the war left no observable legacies in heavily bombed regions. For one thing, more heavily bombed provinces have higher membership in war veterans' associations – in a specification analogous to Table 6 regression 1, the point estimate is 0.00022, standard error 0.00011 – and there is suggestive, though not always significant, evidence that 2002 disability rates are somewhat higher (regressions not shown), perhaps in part due to war and landmine/UXO injuries.

5.3 Impacts on Population Density

Total U.S. bombing intensity is not significantly related to 1999 province population density (Table 8, regression 1), with a point estimate of 0.13 and standard error 0.49. Provinces that had high population densities in 1960-61 also tend to have high density in 1999 (the point estimate on 1960-61 density is 0.89, standard error 0.19) as expected, and former South Vietnam has somewhat higher 1999 population density overall, although that effect is only marginally significant. In this province level specification, the effect of a change from zero up to average province level U.S. bombing intensity is $(30.6) \times (0.13) = 4.0$ additional people per km², a miniscule effect of less than 0.01 of a standard deviation in 1999 province population density, with a tight 95% confidence range from -26 to +34 people per km².

Total U.S. bombing intensity is not statistically significantly related to 1999 district population density in district level OLS specifications (Table 8, regression 2-4). Similarly, in neither the reduced form regression of population density on the north-south distance from the 17th parallel (regression 5), nor the IV-2SLS specification (regression 6) is the key explanatory variable statistically significantly related to 1999 district population density. However, one caveat to all of the district level population results are the large standard errors on the key coefficient estimates, which make these estimates far less precise than the poverty results reported above (in Tables 4 and 5). The leading explanation for these large standard errors in the district level regressions is the absence of a prewar *district* level population density control: 1960-61 province population density is only weakly correlated with 1999 district population density.

There is similarly no statistically significant effect of bombing on 1999 district population density in several other samples and specifications, including in former North Vietnam and South Vietnam, in rural areas (districts with baseline population density less than 200 per km²), when province fixed effects are included, and using alternative measures of bombing intensity (regressions not shown). The estimated effect of bombing is sometimes positive for urban areas but the result is not robust (not shown).

We next trace out effects on population density over time from 1985 to 2000 using Vietnamese Statistical Yearbook data, and find no effect of bombing intensity on population density in 1985 (Table 9, Panel A). We also find no effects on province population density growth rates from 1985 to 2000 (Panel B). So unlike for consumption, there is no evidence of “catch-up” population growth. Moreover, as was the case for 1999 population, there is no statistically significant effect of U.S. bombing on province population in any year from 1985 to 2000 (results not shown). This suggests that if there were any large postwar population movements into the more heavily bombed regions, they must have occurred prior to 1985. Unfortunately, disaggregated population figures are incomplete for the 1970s and early 1980s, preventing us from extending the analysis back to the

immediate postwar period. Thus it remains possible that there were in fact short run localized effects of the war on population that had dissipated by 1985.

It is plausible that this lack of population effects is due to large postwar inflows of migrants into heavily bombed districts, but while we cannot rule this out, nor do we find any compelling evidence that it is in fact the case. Using the 1997/8 VLSS, U.S. bombing intensity does not have a consistent effect on the proportion of individuals not born in their current village of residence (Table 9, Panel C) although the point estimate is positive and marginally statistically significant in one specification (regression 2). The leading interpretation of the data is that most households displaced by the war simply returned to their home areas after conflict had ended.

6. Discussion: Why No Long-run Local Impacts?

Why does the most intense bombing campaign in human history seemingly have no adverse local economic consequences 25 years later? There are a variety of explanations, based on the empirical analysis as well as our reading of the historical literature. First, much U.S. bombing targeted South Vietnam with the purpose of impeding the progress of enemy troops (both North Vietnam Army and NLF/Vietcong guerrillas) and took place in rural areas (Tilford 1991: 105-6). These areas had little fixed infrastructure to destroy, and instead bombing often led to the destruction of forest and farmland, much of which could be expected to recover naturally over time. Even U.S. military planners recognized early in the war that “the agrarian nature of the [Vietnamese] economy precludes an economic collapse as a result of the bombing” (*Pentagon Papers* 1972: 232).

Even if the impact of bombing on infrastructure in rural areas was not as devastating as the bombing intensity numbers suggest, one should not underestimate the ingenious strategies employed by the North Vietnamese to limit the damage to physical infrastructure that did occur, especially in urban areas. First of all, some industrial operations were dispersed across multiple sites (Kamps 2001: 70). Second, according to Tilford (1991: 112) “[r]oads (such as they were) were quickly

repaired. Bridges were bombed often but, in addition to being difficult to hit, were easily bypassed with dirt fords, underwater bridges, and pontoon bridges.” In North Vietnam up to half a million people worked rebuilding infrastructure destroyed by U.S. bombing (Herring 2002: 176).

Another important factor counteracting the effects of U.S. bombing was the major Vietnamese government reconstruction effort after the war, with massive mobilization of labor and resources to rebuild damaged infrastructure and demine the countryside (World Bank 2002). Although we lack district-level investment data, government yearbooks contain information on total state investment by province during 1976-1985. For 1985 alone we are able to construct per capita state investment figures (complete province population data is only available for 1985), and we find that more heavily bombed provinces did in fact receive somewhat more investment (in millions of 1985 Dong per capita): in a specification analogous to Table 6, column 1, the point estimate on total U.S. bombing intensity is 0.0113 (standard error 0.0071, regression not shown), and this effect is nearly statistically significant at 90% confidence. This is a large effect: going from zero to average province level bombing intensity leads to an increase of 1.5 standard deviations in state investment.

Similarly, over the entire 1976-1985 period, the ratio of state investment flows for provinces above versus below the median in terms of U.S. bombing is 2.0. In other words, the more heavily bombed provinces received twice as much state investment on average. As one can see in Figure 3, this ratio increases rapidly after 1980, with the end of the border conflict with China and the complete occupation of Cambodia, suggesting that the redistribution of state investment across regions became stronger when more resources were available. These patterns provide further evidence that the Vietnamese government attempted to allocate additional resources to heavily bombed regions. This may explain some of the gains in electricity infrastructure and may also have laid the foundation for the rapid catch-up growth in consumption discussed above.

In terms of population, the displacement caused by bombing seems to have been mostly temporary. Vietnamese communities developed elaborate responses to avoid injury during periods of

intense U.S. bombing, including hiding for extended periods in well provisioned bomb shelters and in underground tunnels – thousands of miles of which were built during the war – while others fled temporarily before returning to rebuild (Herring 2002: 174-176).

Finally, despite the war, large-scale school expansion and literacy campaigns were carried out during the 1960s and 1970s, especially in North Vietnam, where promoting literacy was a central social goal of the regime (Ngo 2004). Since school infrastructure was vulnerable to U.S. bombing, teachers and students dispersed into small groups to avoid strikes, and schools often had foxholes and helmets for students' protection during U.S. attacks (Duiker 1995, Nguyen Khac Vien 1981).

These results taken together are broadly in line with the predictions of the neoclassical growth framework: a loss of factor endowments due to war led to rapid catch-up growth and convergence back to the steady state, as proxied by performance in regions that suffered hardly at all from U.S. bombing. There is no evidence of a local poverty trap. The electricity infrastructure results are consistent with a vintage capital growth model but we feel that distinguishing between the vintage and neoclassical models is less fundamental than our main finding of no long-run local economic impacts. The most provocative result, and one that resonates with Davis and Weinstein (2002) and others in this emerging literature, is that the transition back to the economic steady state can be extremely rapid even after massive bombing.

7. Conclusion

We find no robust long run impacts of U.S. bombing on local poverty rates, consumption levels, or population density in Vietnam over 25 years after the end of the “American War”. Given that the bombing of Vietnam was the most intense bombing episode in world history, this is a surprising result. There is evidence of substantial reallocation of Vietnamese government resources towards the regions that were more heavily bombed, and this can plausibly explain at least part of the result.

As discussed above, our empirical approach compares more heavily bombed areas to other areas and thus cannot estimate nation-wide war effects on Vietnamese economic development. The counterfactual – national Vietnamese economic outcomes in the absence of the war – is impossible to reconstruct. If the regions not greatly affected by the war assisted the more heavily bombed regions through postwar resource transfers, as state investment data suggest, then differences between the more and less heavily bombed areas would be dampened but overall Vietnamese living standards could still have fallen. In that case, the actual aggregate effects of U.S. bombing on long run Vietnamese economic performance would be more negative than our estimates imply.

The legacy of the war has clearly not prevented Vietnam from achieving rapid economic growth: Vietnamese growth in GDP per capita has recently been among the fastest in the world, at 6% per year between 1993 and 2003 (World Bank 2004), following the reforms of the 1980s and 1990s. Our data indicate the 1990s were a crucial period of economic convergence across regions.

Caution is called for in drawing broad lessons regarding war's impacts on economic growth in general. Unlike many other poor countries, postwar Vietnam benefited from relatively strong and centralized political institutions with the power to mobilize human and material resources in the reconstruction effort. Countries with successful postwar recovery experiences are also probably more likely to collect the sort of systematic economic data that make this study possible. This may lead to selection bias: war-torn countries where the economy and institutions have collapsed (e.g., Democratic Republic of Congo or Somalia) lack such data, preventing the estimation of any persistent local war impacts in those societies.

Vietnam also emerged successfully from war out of a long struggle for national liberation⁸ against foreign occupiers (first the French and later the United States), an experience that fostered a strong sense of nationalism that could be mobilized in the postwar reconstruction. In contrast, the

⁸ The conflict in Vietnam was a combination of a war of national liberation and a civil conflict between the North and the South, but the postwar political rhetoric of the victorious North usually emphasized the former.

bulk of wars in the world today are internal civil conflicts, which may exacerbate political and social divisions and weaken national institutions rather than strengthen them. Some recent research suggests that the low-level civil conflict in the Basque region of Spain has significantly reduced economic growth there relative to neighboring regions (Abadie and Gardeazabal 2003), for example. Collins and Margo (2004) find that the destructive U.S. race riots of the 1960s had lingering effects on the average income of local African-Americans up to twenty years later. The world's most conflict prone region today is Sub-Saharan Africa, where state institutions are notoriously weak (Herbst 2000). In such a setting, postwar reconstruction may drag on far longer than in Vietnam (or in Japan, where postwar political institutions were also strong) leading to more persistent adverse legacies of war. Due to the uniqueness of each society's institutions, politics, and history, in our view further empirical evidence accumulated across cases is needed before general claims about the effects of war on long run economic performance can be made with confidence.

Appendix Figure 1: Raw DSCA bombing data, Quang Tri province

Data Appendix

(1) U.S. Military data

The bombing data in this paper are derived from the following files, housed at the National Archives in Record Group 218, “Records of the U.S. Joint Chiefs of Staff”:

Combat Activities File (CACTA)

- October 1965 – December 1970; November 1967 not available. Monthly. Derived from Combat Activities Reports II/III (COACT II/III), detailing daily air combat operations flown by the US Navy, Marine Corps, and Pacific Air Forces. Carter et al. (1976) list data cards for Army and USMC helicopters as primary input sources.

Southeast Asia Database (SEADAB)

- January 1970 – June 1975. Daily records of allied air combat activities flown by the US Army, Navy, Air Force, and Marine Corps, as well as the (South) Vietnamese Air Force, Royal Lao Air Force, and Khmer (Cambodian) Air Force. Includes both fixed-wing aircraft and helicopters.

Combat Naval Gunfire File (CONGA)

- March 1966 – January 1973. Records of naval gunfire support in North and South Vietnam.

To the best of our knowledge, these data cover all air combat operations flown by all allied forces involved in the Second Indochina War, including Thai and Australian. Some of the original tape archives were damaged, so several months of data may be missing.

The data are geocoded at the district level, employing the codes and boundaries used by the General Statistical Office in the 1999 Population and Housing census. The air ordnance data are divided into 16 categories by type: ammunition, cannon artillery, chemical, cluster bomb, flare, fuel air explosive, general purpose (iron bomb), grenade, incendiary, mine, missile, other, rocket, submunition, torpedo, and unknown. All entries denote number of units, rather than weight, of ordnance expended by district. Nearly all entries denote single units; most ammunition-class entries denote thousands of units. The naval gunfire data are divided into approximately forty specific categories.

Type of ordnance, quantity of ordnance, and drop location were originally recorded by the pilots and gunners who fired the weapons. Such records were created every time ordnance was expended. The data were reported to Pacific Command and ultimately the Joint Chiefs, who declassified the CACTA, SEADAB, CONGA files in 1975, after which they were sent to the National Archives.

The data were provided by Tom Smith at the Defense Security Cooperation Agency (DSCA), in cooperation with Michael Sheinkman of the Vietnam Veterans of America Foundation (VVAFA). We are indebted to Tom Smith, Michael Sheinkman, and Bill Shaw A01 (AW) USN (ret.) for their assistance in understanding the data. VVAFA sought and obtained permission from the Technology Center for Bomb and Mine Disposal (BOMICO), a department of the Engineering Command of the Vietnam Ministry of Defense to provide us the data.

Clodfelter (1995: 216-7) summarizes U.S. ordnance: “Most bombs dropped by U.S. aircraft were either 750-pounders (favored by the U.S. Air Force) or 500-pounders (favored by the U.S. Navy), but bombs of up to 2,000 pounds and other ordnance of unconventional design and purpose were employed. Included among America’s air arsenal were antipersonnel bombs whose outer casing opened to release a string of small warheads along a line of one hundred yards. Some of the other U.S. antipersonnel and high-explosive bombs were the Lazy Dog, which exploded thirty yards above the ground to release a steel sleet of hundreds of tiny darts; cluster bombs, which were ejected from large canisters by small explosive charges after they had penetrated the upper canopy of the forest; and Snake Eyes, which oscillated earthward under an umbrellalike apparatus that retarded the rate of fall long enough to allow the bombing aircraft to come in low with its bomb load and then escape the resulting effects of the detonation.” The following table provides more details.

Appendix Table 1: U.S. Ordnance Categories

Ordnance category	Description
General purpose bombs	Conventional iron bombs, free-falling and unguided. “These account for the greatest fraction of the total weight of aerial munitions used; they are carried by fighter-bombers, attack bombers, and high-flying strategic bombers (B-52s), and delivered by free fall. ... Weight ranges from 100 pounds to 3000 pounds; most common range is 500-1000 pounds; about 50 percent of weight is explosive. The bomb works mostly by blast effect, although shrapnel from the casing is also important. ... The crater from a 500-lb. bomb with impact fuze (e.g., MK 82) is typically 30 feet in diameter and 15 feet deep (this obviously varies greatly with the terrain). Shrapnel is important over a zone about 200 feet in diameter. Simple shelters (sandbags, earthworks, even bamboo) protect against all but close hits.” (Littauer et al 1972: 222). “The biggest of [the GP bombs] was the 15,000-pound BLU-82B ‘Daisy Cutter’.” (Doleman 1984: 127)
Cluster bombs	Cluster bomb units (CBUs) scatter the submunitions they contain—ranging from under forty to over 600 in number—over a wide area, yielding a much broader destruction radius than conventional iron bombs. The outer casing is “blown open (by compressed gas) above ground level (typically 500-foot altitude), distributing bomblets over an area several hundred feet on a side.” (Littauer et al 1972: 222). In our dataset these are primarily fragmentary general purpose, anti-personnel, and anti-material weapons, and occasionally tear gas or smoke, ranging in total bomb weight from 150 to over 800 lbs.
Missiles	Self-guided air-deployed munitions. Includes self-propelled air-to-air and air-to-ground missiles (that typically hone in on radiation from engines or radar) as well as free-fall “smart bombs” (guided toward their targets by laser reflection or electro-optical imaging, e.g., AGM-62 “Walleye”). “The most important anti-radiation air-to-ground missiles used by the U.S. forces in Vietnam were the AGM-45 Shrike and AGM-78 Standard ARM. Radar-directed like the Sparrow, the Shrike was carried by navy and air force jets, including the Wild Weasels. Its purpose was to knock out the ground radar stations that controlled the deadly SAMs and radar-guided anti-aircraft guns.” (Doleman 1984: 125).
Rockets	Self-propelled unguided munitions. “The most common size is 2.75" diameter, delivered singly or in bursts from tubes mounted under the aircraft. Accuracy of delivery is generally higher than for free-fall weapons. Warheads include fragmentation (flechette), high explosive (including shaped charge against armored vehicles), and incendiary action (most white phosphorus or plasticized white phosphorus, PWP). Phosphorus may be used as anti-personnel weapon, but also serves to generate white smoke (often for target designation for further strikes).” (Littauer et al 1972: 223)

Cannon artillery	High-velocity projectiles too large to be labeled ‘Ammunition’. Chiefly, high explosive shells from 105mm Howitzers. (Sources: personal communication with Bill Shaw, 4/16/04)
Incendiaries / white phosphorus	Napalm fire bombs and white phosphorus smoke bombs (<5%). Total fire bomb weights range from 250lb to 750lb, containing between 33-100 gallons of combustible napalm gel. Napalm was primarily successful as a wide-area anti-personnel weapon: “Most effective against entrenched infantry, napalm gave off no lethal fragments and could be used close to friendly forces without the dangers of fragmentation posed by conventional bombs. Often the fire from napalm would penetrate jungle that was immune to shrapnel. A single napalm canister spread its contents over an area a hundred yards long.” (Doleman 1984: 127)
Land mines	Primarily air-dropped ‘Destructor’ mines. “Destructor Mines are general purpose low-drag [GP] bombs converted to mines. They can be deployed by air, either at sea as bottom mines or on land as land mines. ... When dropped on land, they bury themselves in the ground on impact, ready to be actuated by military equipment, motor vehicles and personnel. When dropped in rivers, canals, channels, and harbors, they lie on the bottom ready to be actuated by a variety of vessels including war ships, freighters, coastal ships, and small craft.” (FAS 2004) With just over 55,000 mines listed for the entire country in our dataset, compared with an outside estimate of 3,500,000 mines (UNMAS 2004), our data capture a trivial fraction of total presumed landmine presence in Vietnam. This is likely because a large share of landmines were placed in the ground by U.S. army troops.
Ammunition (000’s of rounds)	Projectiles fired from air at high-velocity. Cross-sectional diameter (caliber) ranges from 5.56mm to 40mm, spanning the traditional categories of small-arms (≤ 0.50 caliber/inches = 12.7 mm), regular ammunition, and cannon artillery (≥ 20 mm). (Sources: FAS (2004); personal communication with Bill Shaw, 4/16/04)

(2) Vietnam Poverty, Geographic, and Climatic Data

District-level estimates of poverty were provided by Nicholas Minot of the International Food Policy Research Institute (IFPRI). The estimates were generated through poverty mapping, an application of the small-area estimation method developed in Elbers et al (2003). This method matches detailed, small-sample survey data to less-detailed, large-sample census data across geographic units, to generate area-level estimates of an individual- or household-level phenomenon—in our case, district-level poverty incidence in Vietnam. For more detailed information, see Minot et al. (2003).

The two datasets used by Minot et al. (2003) are the 1997/8 Vietnam Living Standards Survey (VLSS) and a 33% subsample (5,553,811 households) of the 1999 Population and Housing Census. The VLSS, undertaken by the Vietnam General Statistical Office (GSO) in Hanoi with technical assistance from the World Bank, is a detailed household-level survey of 4270 rural and 1730 urban Vietnamese households. The 1999 Population and Housing Census was conducted by the GSO with technical support from the United Nations Family Planning Agency and United Nations Development Program (UNDP). We also use data from the 1992/3 and 2002 VLSS survey rounds in this paper.

Minot et al. use the VLSS data to estimate a household-level, log-linear regression of real cost-of-living-adjusted per capita consumption expenditure on 17 household characteristics common to both the VLSS and the Population and Housing Census. These characteristics include: household size, proportion over 60 years old, proportion under 15 years old, proportion female, highest level of education completed by head of household, whether or not head has a spouse, highest level of education completed by spouse, whether or not head is an ethnic minority, occupation of head over last 12 months, type of house (permanent; semi-permanent or wooden frame; “simple”), house type interacted with living area, whether or not household has electricity, main source of drinking water, type of toilet, whether or not household owns a television, whether or not household owns a radio, and region. Minot et al. (2003) partition the sample to undertake separate parameter estimates for the correlates of rural and urban poverty.

Predicted consumption expenditures per capita for each of the district-coded households in the 1999 Population and Housing Census sample are then generated using the parameter estimates from these regressions. Properly weighting by the size of each household, this enables Minot et al (2003) to generate an estimate of district-level poverty incidence, the percentage of the population in each district that lives below the official national poverty line of 1,789,871 Dong (VND) per person per year (GSO 2000).

All district-level topographic, geographic, and climatic data used in this paper were provided by Nicholas Minot and are identical to those used in Minot et al. (2003). The topographical data used in Minot et al. (2003) are taken from the United States Geological Survey.

Province population figures in the 1980s and 1990s are from the Vietnam Statistical Yearbooks (Vietnam General Statistical Office). Unfortunately, we have been unable to locate complete and consistently defined province level demographic data from the mid-1970s through the mid-1980s. These Yearbooks also contain information on total state investment flows by province from 1976-1985, data that is also used in the statistical analysis.

(3) Data from the pre-“American War” period

Pre-war, province-level demographic data on South Vietnam were taken from the 1959-1965 editions of the *Statistical Yearbook of Vietnam*, published by the National Institute of Statistics in Saigon, and for North Vietnam from the *Vietnam Agricultural Statistics over 35 Years (1956-1990)*, published by the GSO Statistical Publishing House in Hanoi (1991). Province level agricultural statistics are also available (e.g., rice paddy yields), but it is widely thought that such prewar data are unreliable as a result of the prewar ideological conflict between North and South Vietnam (Banens 1999), and thus we do not use those data in the analysis.

A final data source we considered is the HAMPLA/HES database collected by the U.S. government starting in South Vietnam in 1967-68 (described in Kalyvas and Kocher 2003), which collected rough proxies for village socioeconomic conditions. The two main drawbacks of this data is that first, the exact procedure for assigning the local SES measures is not transparent or well-described in existing sources, and second the data was collected several years into the war, and thus may be endogenous to earlier U.S. bombing patterns. For these reasons we do not utilize this data in the analysis.
