Do Tax Filers Bunch at Kink Points?  
Evidence, Elasticity Estimation, and Salience Effects

April 22, 2009

Abstract

This paper uses individual tax return micro data from 1960 to 2004 to analyze whether taxpayers bunch at the kink points of the U.S. income tax schedule generated by jumps in marginal tax rates. We develop a method to estimate the compensated elasticity of reported income with respect to (one minus) the marginal tax rate using bunching evidence. We find clear evidence of bunching around the first kink point of the Earned Income Tax Credit with implied estimated intensive earnings elasticity around 0.25. The response is concentrated among those with self-employment income with elasticities around one which grow overtime (presumably as tax filers learn about the schedule). The elasticities are always equal to zero for wage earners. We develop a simple modelling of reporting to account for those results. We also find evidence of bunching at the threshold of the first tax bracket where tax liability starts, especially in the 1960s when the tax schedule was stable and simple. However, there is no evidence of bunching at all for other kink points of the tax schedule, even when the tax brackets are stable over many years and where jumps in marginal tax rates are substantial. We conclude that simplicity and saliency is critical to observe bunching at kink points.

1 Introduction

A large body of empirical work in labor and public economics analyzes the behavioral response of earnings to taxes and transfers using the standard model where agents choose to supply hours of work until the marginal disutility of work equals marginal utility of disposable (net-of-tax) income. This model predicts that, if individual preferences are convex and smoothly distributed in the population, we should observe bunching of individuals at convex kink points of the budget set. Taxes and government transfers create such kink points. The progressive US individual income tax generates a piece-wise linear budget set with kinks at each point where the marginal tax rate jumps. Means-tested government transfer programs also introduce piecewise-linear constraints because transfer benefits are “taxed” away as income rises. For example, the Earned Income Tax Credit (EITC) creates two large convex kink points at the points where the credit is fully phased-in, and where it starts being phased-out. Looking for bunching evidence around kinks provides a simple test of the validity of the widely used standard model and of the presence of behavioral responses to taxation along the intensive margin. Furthermore, the amount of bunching generated by budget set kinks is proportional to the size of the compensated elasticity of income with respect to the net-of-tax rate.

The present paper has therefore two goals. First, we investigate thoroughly whether there is evidence of bunching at the kink points of the US federal income tax, as well as the determinants of bunching. Second, we develop an econometric method to estimate compensated elasticities of reported income with respect to net-of-tax rates using bunching evidence. Our empirical analysis uses the large annual tax return data publicly released by the Internal Revenue Service (IRS) since 1960. We obtain three main empirical results.

First, we find clear evidence of bunching around this first kink point of the EITC—the point at which the credit reaches its maximum level—with an implied elasticity of earnings around 0.25. Such bunching evidence constitutes perhaps the most compelling evidence to date of behavioral responses created by the EITC along the intensive margin. However, we find that

---

1Feldstein (1999) shows that this model can be extended to analyze not only the choice of hours of work but more generally the response of overall income to marginal tax rates.

2Those administrative data are ideally suited for the analysis because they provide information about the exact location of taxpayers on the tax schedule and, in contrast to standard survey data, have almost no measurement error.

3A large body of work has shown strong evidence of behavioral responses to the EITC along the extensive margin, i.e. the decision to participate in the labor force. Evidence of behavioral responses along the intensive
bunching is concentrated among EITC recipients with self-employment income with a very large implied elasticity around one. EITC wage earners display no evidence of bunching and thus the implied elasticity for wage earners is zero (and precisely estimated). This suggests that most of the bunching response might be due to reporting effects rather than real labor supply effects. 4 Furthermore, the amount of bunching grows overtime (the EITC schedule has been stable since the major expansion of 1993-1996) suggesting that tax filers learn slowly about the EITC schedule. 5 Second, we also find evidence of bunching at the threshold of the first tax bracket where tax liability starts, especially in the 1960s when the tax schedule was stable and very simple. The implied elasticities are also significant in that case, around 0.2. Part of the elasticity is due to the response of itemized deductions are the evidence of bunching is not as sharp for taxable income recomputed using always the standard deduction (instead of the maximum of the standard deduction and itemized deductions). Third, however, we cannot find any bunching evidence for other kink points of the tax schedule, even when jumps in marginal tax rates are large and stable over many years, and even when restricting the sample to more responsive sub-groups such as those reporting self-employment income.

Therefore, our evidence shows that taxpayers behave as in the standard labor supply model only when the tax system is very simple and salient. The first kink of the EITC is simple because there is no interaction with the income tax (as the EITC is fully refundable). The first kink of the EITC is salient because, for many eligible families, it is the level of earnings that maximizes the tax refund. The first kink point of the income tax schedule is also salient because this is the income level where tax liability starts and hence is much more visible on tax tables than kink points at higher income levels. Because the federal income tax is so complicated, such simple and salient situations where taxpayers behave as in the standard model are the exception rather than the norm. Indeed, survey evidence suggests that many taxpayers do not know their marginal tax rate or report it with substantial error (see e.g., Fuji and Hawley, 1988 for US evidence and Liebman and Zeckhauser 2004 for a brief survey).

Our analysis relates to the nonlinear budget set labor supply estimation method. 6 This margin (i.e., hours of work conditional on working) is weak or absent (see Eissa and Hoynes (2006) and Hotz and Scholz (2003) for recent surveys).

4 We develop a simple model of reporting which can account for our empirical findings.

5 Those results are consistent with the recent and complementary analysis by Lalumia (2009) which shows that EITC expansions lead to an increase in the fraction of low income filers with children reporting self-employment income.

6 First developed by Burtless and Hausman (1978) to study the Negative Income Tax experiments, Hausman
method was originally developed to address the endogeneity of the marginal tax rate to the labor supply choice (as higher labor supply may push the individual into a higher tax bracket). In that context, nonlinear budget sets were seen as a source of endogeneity problems which had to be solved using a structural model rather than an opportunity to identify behavioral responses to taxation as in our analysis.

No study has carefully examined the evidence of bunching at the kink points of the US income tax schedule to uncover evidence of behavioral responses, in spite of data availability. A recent study by Chetty et al. (2009) uses tax return data from Denmark and uncovers substantial bunching at a large kink point of the Danish income tax schedule where the top rate starts to apply. This kink point is simple and salient because it is large and the same for all individuals. Consistent with our US results, they do not find much evidence of bunching at smaller kink points of the tax schedule.

A few other studies have documented evidence of bunching at the kink points generated by other government programs. First, Burtless and Moffitt (1984) and Friedberg (2000), using Current Population Survey data, observed bunching behavior in the case of elderly individuals who receive social security benefits but are still working and subject to the Social Security earnings test. Those studies however do not use bunching to estimate compensated elasticities as we do here. They instead rely on the standard nonlinear budget set method for estimating behavioral responses. Second, Blundell and Hoynes (2004) document clear evidence of bunching at exactly 16 hours per week for individuals likely to be eligible for the family credit which imposes a 16 hours minimum working requirement. Finally, pension programs also generate kinks (or cliffs) in the lifetime budget set. As is well known, retirement hazard rates display bunching at certain ages related to the parameters of the retirement programs.

7US tax return data have been available for a long time but rarely used by labor economists. As pointed out by Hausman (1982), in defense of the nonlinear budget set methods and in response to a criticism by Heckman (1982) who argued that no bunching evidence could be found in the data, survey data have too much measurement error to study bunching precisely.

Chetty et al. (2009) argue that part of the bunching might be driven by employers’ pay policies which are tailored to avoid the top bracket, which is feasible in Denmark as the top bracket threshold is uniform across all individuals.

Social security benefits are taxed away (actually deferred) when earned income exceeds an exemption amount. Tax rates vary from 33% to 50% and thus generate substantial kinks in the budget set of the elderly. This phasing-out structure is very simple and hence likely to be very salient to social security beneficiaries.

For example, in the United States, there is bunching at the early retirement age of 62 (when workers become eligible to claim Social Security benefits) and bunching at the normal retirement age (see Gruber and Wise...
Those studies point out that bunching is evidence of behavioral responses to pension programs although they do not directly use bunching to estimate elasticities. A recent notable exception is Brown (2007) who uses changes in the kink points due to reforms in the California Teachers retirement program to estimate elasticities of retirement age with respect to price incentives. In contrast to our study, Brown (2007) uses reforms and corresponding changes in bunching behavior to estimate elasticities while we focus on a more basic cross-sectional estimation method.

The paper is organized as follows. Section 2 presents the conceptual framework, the data, and discusses the estimation methodology. Section 3 presents the EITC based results. Section 4 presents results based on the regular federal income tax schedule. Section 5 concludes.

2 Model, Data, and Methodology

2.1 Model and Small Kink Analysis

Consider the standard model with two goods where individuals' utility functions depend positively on after-tax income $c$ (individuals value consumption) and negatively on before-tax income $z$ (earning income requires effort). We assume that, with a linear budget set with constant marginal tax rate $t$, individual incomes $z$ are distributed according to a smooth density distribution $h(z)$. The heterogeneity in earnings $z$ is due to differences in preferences or ability—both of which are captured by heterogeneity in the utility function $u(c, z)$ across individuals.

Suppose that a (small) kink is introduced in the budget set at income level $z^*$ by increasing the marginal tax rate from $t$ to $t + dt$ for incomes above $z^*$ as depicted on Figure 1A. Such a kink is going to produce bunching of individuals whose incomes were falling into a segment $[z^*, z^* + dz^*]$ before the kink was introduced as displayed on Figure 1B. The individual (denoted by $L$ on Figure 1) with earnings $z^*$ before the tax change is not affected and his indifference curve remains tangent to the lower part of the budget set (with slope $1 - t$). Let us denote by $H$ the highest income earner (before the tax change) who is now bunching at the kink. Before the tax change, individual $H$ had earnings $z^* + dz^*$ and his indifference curve was tangent to the linear budget with slope $1 - t$ as shown in Figure 1A. After the tax change, his indifference curve is exactly tangent to the upper part of the budget set (slope $1 - t - dt$) as depicted on (1999) for an analysis across a number of countries).
Figure 1A. For a small change in the marginal tax rate $dt$, by definition of the compensated elasticity $e$ of earnings with respect to one minus the tax rate, we have

$$\frac{dz^*}{z^*} = e \cdot \frac{dt}{1-t}. \quad (1)$$

Thus the total number of taxpayers bunching at $z^*$ is simply $h(z^*)dz^*$ where $h(z^*)$ is the density of incomes at $z^*$ when there is no kink point and $dz^*$ is given by equation (1). This derivation shows that bunching is proportional to the compensated elasticity $e$ and to the net-of-tax ratio $dt/(1-t)$. Note that in the case of large jumps (when $dt/(1-t)$ is no longer small), there would be income effects and the elasticity $e$ would no longer be a pure compensated elasticity but a mix of the compensated elasticity and the uncompensated elasticity. Three important points should be noted.

First, the larger the behavioral elasticity, the more bunching we should expect. Unsurprisingly, if there are no behavioral responses to marginal tax rates, there should be no bunching at all. Thus, within the standard model, this central elasticity could in principle be estimated by measuring the amount of bunching at kinks of the tax schedule.

Second, the size of the jump in marginal tax rates is measured by the change in marginal tax rates relative to the base net-of-tax rate $1-t$. Thus, everything else being equal, a change in marginal tax rates from 0 to 10% should produce the same amount of bunching than a change from 90% to 91%.

Third, our derivation assumed implicitly that all individuals had the same elasticity $e$. In the case of heterogeneous elasticities across individuals, the amount of bunching remains proportional to the average compensated elasticity at income level $z^*$. To see this, our previous derivation shows that an individual with compensated elasticity $e$ (at $z^*$) bunches at the (small) kink if and only if he/she chooses earnings $z \in [z^*, z^* + e \cdot z^* \cdot \frac{dt}{1-t}]$ under the linear tax at rate $t$.\(^{11}\)

With a heterogeneous population and the linear tax at rate $t$, there will be a joint distribution of earnings $z$ and compensated elasticities $e$ across individuals (as individuals with earnings $z$ might have different elasticities) which we denote by $\psi(z,e)$. We have $h(z^*) = \int e \cdot \psi(z^*,e) de$, and we denote by $\bar{e} = \int e \cdot \psi(z^*,e) de/h(z^*)$ the average compensated elasticity at earnings level $z^*$ (again under the linear tax rate scenario). When a small kink is introduced at $z^*$, the

\(^{11}\)This is true even if the compensated elasticity $e$ for the individual is not constant as changes in $e$ in the small segment $[z^*, z^* + e \cdot z^* \cdot \frac{dt}{1-t}]$ would only introduce second order negligible effects.
number of individual bunching at $z^*$ is $dB = \int e \cdot z^* \cdot \frac{dt}{1-t} : \psi(z^*, e) de = \bar{\epsilon} \cdot h(z^*) \cdot z^* \cdot \frac{dt}{1-t}$ which generalizes (1).

2.2 Empirical Estimation of the Elasticity using Bunching

Because actual kink points are not necessarily small as in our previous analysis, it is useful to consider a simple parametrized model with a quasi-linear and iso-elastic utility function of the form

$$u(c, z) = c - \frac{n}{1+1/e} \cdot \left(\frac{z}{n}\right)^{1+1/e},$$

where $n$ is an ability parameter distributed with density $f(n)$ (and cumulated distribution $F(n)$) in the population (normalized to one). The quasi-linearity assumption implies that there are no income effects so that compensated and uncompensated elasticities are equal. This simplifies considerably the presentation at little cost because bunching essentially identifies the compensated elasticity as we discussed above. The iso-elasticity assumption implies that the elasticity is constant and equal to $e$ which simplifies the presentation without affecting the substance of the results.

Maximization of $u(c, z)$ subject to a linear budget constraint $c = (1-t) \cdot z + R$ leads to the first order condition: $1 - t - \left(\frac{z}{n}\right)^e = 0$ which can be rewritten as

$$z = n \cdot (1 - t)^e.$$  

(2)

Therefore, with no marginal tax rates ($t = 0$), we have $z = n$ so that $n$ can be interpreted as potential earnings. Positive tax rates depress earnings $z$ below potential earnings $n$ as shown in (2).

Let $H_0(z)$ be the cumulated distribution of earnings when there is a constant marginal tax rate $t_0$ throughout the distribution. Let us denote by $h_0(z) = H'_0(z)$ the corresponding density distribution. We have $z = n \cdot (1 - t_0)^e$ and therefore $H_0(z) = Prob(n \cdot (1 - t_0)^e < z) = F(z/(1 - t_0)^e)$, and hence $h_0(z) = f_0(z/(1 - t_0)^e)/(1 - t_0)^e$.

Let us introduce a (convex) kink in the budget set by increasing the marginal tax rate to $t_1$ (with $t_1 > t_0$) above earning level $z^*$. Let us denote by $h(z)$ the density of realized earnings and $H(z)$ the cumulated distribution under this kinked budget set scenario.

With the kink, we still have $z = n \cdot (1 - t_0)^e$ below $z^*$, i.e., for $n < z^*/(1 - t_0)^e$ so that $h(z) = h_0(z)$ for $z < z^*$. However, we have $z = n \cdot (1 - t_1)^e$ above $z^*$, i.e., for $n > z^*/(1 - t_1)^e$. 6
Therefore, for \( z > z^* \), we have \( H(z) = \text{Prob}(n \cdot (1 - t_1)^e < z) = F(z/(1 - t_1)^e) \), and hence 
\[
h(z) = f(z/(1 - t_1)^e)/(1 - t_1)^e = h_0 \left( z \cdot \left( \frac{1-t_0}{1-t_1} \right)^e \right) \cdot \left( \frac{1-t_0}{1-t_1} \right)^e.
\]
Let us denote by \( h(z^*)_+ \) (resp. \( h(z^*)_+ \)) the left (right) limit of \( h(z) \) when \( z \to z^* \). We have 
\[
h(z^*)_+ = h_0(z^*) = h(z^*)_+ = h_0 \left( z^* \cdot \left( \frac{1-t_0}{1-t_1} \right)^e \right) \cdot \left( \frac{1-t_0}{1-t_1} \right)^e.
\]
Individuals with \( n \in [z^*/(1 - t_0)^e, z^*/(1 - t_1)^e] \) choose \( z = z^* \) and hence bunch at the kink point. The highest ability person who bunches has \( n = z^*/(1 - t_1)^e \) and hence had earnings 
\[z^* \cdot \left( \frac{1-t_0}{1-t_1} \right)^e \]
under the linear tax \( t_0 \) scenario. As a result, any individual earning between \( z^* \)
and \( z^* + \Delta z^* \) under the linear tax \( t_0 \) bunches at the kink under the piecewise linear tax \((t_0, t_1)\),
where
\[
\frac{\Delta z^*}{z^*} = \left( \frac{1-t_0}{1-t_1} \right)^e - 1.
\]
This equation generalizes equation (1) to a large kink. Therefore, the fraction of the population
bunching is
\[
B = \int_{z^*}^{z^*+\Delta z^*} h_0(z)dz \simeq \Delta z^* \cdot \frac{h_0(z^*) + h_0(z^* + \Delta z^*)}{2} = \Delta z^* \cdot \frac{h(z^*)_- + h(z^*)_+}{2} \left( \frac{1-t_0}{1-t_1} \right)^e,
\]
where we have used the standard trapezoid approximation for the integral.
Hence combining (3) and (4) leads to a quadratic equation in \( \left( \frac{1-t_0}{1-t_1} \right)^e \):
\[
B = z^* \cdot \left( \left( \frac{1-t_0}{1-t_1} \right)^e - 1 \right) \cdot \frac{h(z^*)_- + h(z^*)_+}{2} \left( \frac{1-t_0}{1-t_1} \right)^e,
\]
which can be solved explicitly to express \( e \) as a function of observable or empirically estimable
variables: (1) the kink threshold \( z^* \), (2) the net-of-tax ratio \((1 - t_1)/(1 - t_0)\) associated to the
kink, (3) the density of the distribution just below and just above the kink \( h(z^*)_- , h(z^*)_+ \), (4)
the amount of bunching \( B \) at \( z^* \).
Parameters (1) and (2) are directly observable. Therefore, we only need to estimate pa-
rameters (3) and (4) and then apply the Delta method to estimate \( e \) with standard errors. To
estimate \( B \), we need to evaluate how much excess density there is at the kink point \( z^* \). For a
given empirical distribution \( h(z) \), we can define an income band around the kink, \((z^* - \delta, z^* + \delta)\),
and two surrounding income bands \((z^* - 2\delta, z^* - \delta)\) and \((z^* + \delta, z^* + 2\delta)\) below and above the
kink as depicted on Figure 2. The parameter \( \delta \) measures the width of those income bands.
The simplest estimate of excess bunching is the difference between the number of individuals
in the band around the kink and the number of individuals in the two surrounding bands:

\[ B = \int_{z^*-\delta}^{z^*+\delta} h(z)dz - \int_{z^*-2\delta}^{z^*-\delta} h(z)dz - \int_{z^*+\delta}^{z^*+2\delta} h(z)dz. \]  

(6)

Many taxpayers are unable to control perfectly their incomes (due for example to random components such as year-end bonuses or risky returns on assets, or the difficulty of estimating exactly income for tax purposes), or may not be aware of the exact location of kink points. In those cases, we would expect taxpayers to cluster around the kinks instead of bunching exactly at the kink as depicted on Figure 2 (Saez, 1999 develops this point with a formal model of labor supply with uncertain outcomes). In that case, the choice of the parameter \( \delta \) matters when estimating excess bunching \( B \) using (6). If \( \delta \) is too small, the amount of excess bunching due to the behavioral response to the kink will be under-estimated. However, increasing \( \delta \) might also introduce bias as equation (6) ignores second order effects due to the curvature of the underlying density function \( h_0(z) \) (assuming no kink at \( z^* \)). When \( \delta \) is small, such curvature effects are negligible but may be significant when \( \delta \) is large.\(^{12}\)

If, as depicted on Figure 2, the underlying density \( h_0(z) \) is convex at \( z^* \), then formula (6) overestimates excess bunching as convexity implies that \( B \) from (6) is positive, even in the absence of behavioral responses. Conversely, if \( h_0(z) \) is concave at \( z^* \), formula (6) underestimates excess bunching. In principle, it should be possible to correct for curvature bias by estimating curvature in the density below and above the kink by using a Taylor expansion for \( h_0 \) around \( z^* \), a refinement we leave for future research with larger sample size.

Empirically, \( h(z^*)_- \) can be estimated as the fraction of individuals in the lower surrounding band \( (z^* - 2\delta, z^* - \delta) \) divided by \( \delta \). Similarly, \( h(z^*)_+ \) can be estimated as the fraction of individuals in the upper surrounding band \( (z^* + \delta, z^* + 2\delta) \) divided by \( \delta \). We estimate the number of individuals in each of the three bands which we denote by \( \hat{H}_-^*, \hat{H}_+^*, \hat{H}_+^* \) by regressing (simultaneously) a dummy variable for belonging to each band on a constant in the sample of individuals belonging to any of those three bands. We can then compute \( \hat{h}(z^*)_+ = \hat{H}_+^*/\delta \), \( \hat{h}(z^*)_+ = \hat{H}_+^*/\delta \), and \( \hat{B} = \hat{H}_+^* - (\hat{H}_+^* + \hat{H}_+^*) \) to estimate \( \hat{e} \).

We can estimate standard errors using the delta method. Alternatively, we can also compute standard errors using a bootstrap method where we draw a large number \( N \) of earnings distributions according to the empirical earnings distribution \( h(z) \), estimate the corresponding

\(^{12}\)Chetty et al. (2009) use much large samples in Denmark and take into account such curvature by estimating the density non-parametrically outside the bunching segment \([z^* - \delta, z^* + \delta]\).
elasticity $e$ for each of the $N$ draws, and estimate a 5% interval standard error using the distribution of estimated elasticities $e$ across the $N$ draws. As we shall see, because our sample size is large, the delta method and the bootstrap methods generate very similar standard errors.

2.3 Data and Graphical Methodology

As discussed in introduction, the large publicly available annual cross-sections of individual tax returns constructed by the Internal Revenue Service (IRS), known as the Individual Public Use Tax Files, are the ideal data to carry out this study. The data are available quasi-annually from 1960 to 2004. The average number of tax returns per year is between 80,000 and 200,000. The annual cross sections are stratified random samples with high sampling rates for high income taxpayers. Therefore, the data span a long-time and hence a number of different tax schedules. This is of interest because we do not expect taxpayers to adapt immediately to changes in the location of kink points, and repeated cross-sections may allow to study the dynamics of bunching following a tax change.

To detect exact bunching at kink points, the simplest method consists in producing histograms of the distribution with small bins and check whether spikes appear at kink points. Because taxpayers may not be able to bunch perfect at kink points, we might only observe clustering or humps around kink points. In such a scenario, kernel density estimates are helpful to smooth noisy histograms and detect excess clustering.

Note that other transfer programs or state income taxes introduce additional kinks in the budget constraint of tax filers. However, because those programs vary geographically and do not use the same income definition as the EITC or the federal taxable income, those kinks will not be located uniformly across tax filers in our samples and hence any bunching they generate will be smoothed out in the aggregate.

3 EITC Empirical Results

The Earned Income Tax Credit (EITC) is a transfer for low income earners that introduces substantial kinks in the budget constraint as described in Table 1. The EITC, first introduced in 1975, was first expanded after the Tax Reform Act of 1988, and then very substantially expanded in 1993-1995 and has been quite stable since then (see Hotz and Scholz 2003 and Eissa and Hoynes 2006 for detailed descriptions of the EITC and its history). The EITC is
a function of family earnings defined as the sum of wages and salaries and self-employment income, and the number of qualifying children. The EITC first increases linearly with earnings in phase-in range, is maximum in the plateau range, and then decreases linearly with earnings in the phase-out range. The EITC also increases with the number of qualifying children since 1994. As shown in Table 1, since 1995, the phase-in subsidy rate is 34% for those with one child and 40% for those with 2 or more children. After a short plateau range where the EITC is maximum, the EITC is phased out at a rate of 16% (21%) for beneficiaries with one qualifying child (two or more qualifying children). Therefore, the EITC creates very large changes in marginal incentives.

3.1 Graphical Evidence

Figure 3 reports the histograms for earnings of tax filers with one child dependent (Panel A) and two or more children dependents (Panel B) by bins of $500. All histograms are presented using population weights. The graphs also depict the corresponding EITC schedules (as a function of earnings) in dashed lines using the right y-axis as well as the location of the kinks in vertical lines. To obtain a large sample size and hence smoother histograms, the figure combines all years from 1995 to 2004 and indexes earnings to 2008 using the IRS inflation parameters so that the EITC kinks are perfectly aligned for all years.

Two elements are worth noting on Figure 3. First, there is a clear clustering of tax filers around the first kink point of the EITC. In both panels, the density is maximum exactly at the first kink point. The fact that the location of the first kink point differs between EITC recipients with one child versus those with two or more children constitutes strong evidence that the clustering is driven by behavioral responses to the EITC as predicted by the standard model. Second, however, we cannot discern any systematic clustering around the second kink point of the EITC. Similarly, we cannot discern any gap in the distribution of earnings around the concave kink point where the EITC is completely phased-out. This differential response to the first kink point versus the other kink points is at odd with the standard model which predicts that any convex (concave) kink should produce bunching (gap) in the distribution of earnings.

Since 1994, tax filers with no children are also eligible to a modest EITC (maximum benefit of $438 in 2008) with small phase-in and phase-out rates of 7.65%. Hence we ignore EITC beneficiaries with no children in the analysis below.
In Figure 4, we break down the sample of earners into those with non-zero self-employment income versus those zero self-employment income (and hence whose earnings comes only from wages and salaries). We now report kernel density estimates (instead of histograms) to compare densities on the same graph.\textsuperscript{14} The densities are normalized to sum to one.\textsuperscript{15} The contrast between the two groups is striking. The self-employed densities display a huge spike exactly at the first kink point while there is no evidence of bunching at all in the sample of pure wage earners. There is no evidence of bunching at the second kink point or of a dip at the end of the phase-out, even for the self-employed sample.

### 3.2 Elasticity Estimation

Table 2 presents elasticity estimates using bunching evidence around EITC kink points for various samples. The table is organized in 6 columns. The first two columns are for the full sample including both wage earners and the self-employed. The next two columns consider the self-employed (defined as above as those with non-zero self-employment income). The last two columns consider the sample of wage earners (those with no self-employment income). In each of those three groups, the first column is for tax filers with one child while the second column is for tax filers with two or more children.

Panel A displays the elasticity estimates for the 1st, 2nd, and 3rd kink points (respectively) pooling all years 1995-2004 together as on Figures 3 and 4. Our results confirm the findings from the figures. We find significant elasticities around the first kink point for the full sample (0.21 and 0.15 for 1 child and 2+ children respectively). Those significant elasticities are driven entirely by the self-employed who display very large and precisely estimated elasticities (1.1 and 0.8 for 1 child and 2+ children respectively). In contrast, we find elasticities very close to zero and precisely estimated for the sample of wage earners around the 1st kink point. We also find insignificant and precisely estimated elasticities around the 2nd and 3rd kink points in all samples (all workers, the self-employed, or wage earners).

Panel B shows the sensitivity of our results with respect to the choice of the bandwidth

\textsuperscript{14}The artificial drop in the kernel densities at each end of the graph is an artifact of the estimation method due to data truncation.

\textsuperscript{15}The fraction of self-employed in the population depicted on Figure 4 is 16.1\% (for those with one child in Panel A) and 20.2\% (for those with two or more children in Panel B) on average for years 1995-2004. In the data sample, the fractions self-employed are higher (32\% and 40\% respectively) because the data samples overweight tax filers with more complex tax returns.
δ around the first kink point.\textsuperscript{16} The bands corresponding to the baseline δ = $1,500 were depicted on Figure 3 (light dotted vertical lines). They represent a conservative choice of bandwidth leading to an underestimate of the elasticities as the lower and upper bands densities are already affected by the clustering around the kink. Therefore, it is not surprising that increasing the bandwidth to $2,000 leads to even higher estimates, which we view as probably closer to the true elasticity revealed by bunching behavior. Conversely, lowering the bandwidth to $1,000 leads to smaller (but still significant) estimates. This confirms that, in the presence of clustering around a kink point instead of exact bunching, the choice of the bandwidth matters.

In this paper, we use a simple graphical visual approach for selecting the bandwidth. With larger datasets and hence smoother density estimates, it could be possible to devise a method to detect bunching humps statistically and hence choose the bandwidth δ with a systematic method.

Panel C breaks the sample into two periods 1995-1999 versus 2000-2004 as we did in Figure 5. The results confirm the graphical evidence and show that the elasticities more than double from the early period to the late period. However, the elasticities for wage earners remain close to zero and insignificant even in the late period.

Finally, Panel D presents results for the smaller EITC for the period 1988-1993 when the phase-in subsidy rate was much smaller as reported in Table 1, (14% from 1988-1990 and growing slowly to almost 20% from 1991 to 1993). The elasticity estimates are also significant for the first kink point and close to 0.3 for the self-employed. Those elasticity estimates are much lower than for the large EITC period. There is interesting heterogeneity during this “small EITC” period: the elasticity estimate for the self-employed is not significant for the early period 1988-1990 when the EITC rate was 14% while it becomes significant during the years 1991, 1992, 1993 when the EITC rate is 17%, 18%, and 19% (on average). Graphical evidence (omitted for sake of space) shows indeed that there is no sharp spike at the kink point in 1988-1990 but that a spike develops exactly at the kink point in years 1991-1993.\textsuperscript{17}

\textsuperscript{16}The estimates around the 2nd and 3rd kink points are always small and insignificant and not sensitive to δ, and hence omitted to save space.

\textsuperscript{17}Liebman (1998) did not find evidence of bunching at the EITC kink points in 1992 (before the large EITC expansion). However, he did not break down recipients by self-employment status, explaining why, in contrast to our findings, he did not uncover evidence of bunching.
3.3 Interpretation

Our first finding is that wage earners do not display any evidence of responses to the marginal incentives created by the EITC even when the change in marginal incentives is very large and the EITC schedule is stable (as is the case since 1995). This can be explained in three ways. First, wage earners may have a very low intensive elasticity of earnings with respect to marginal tax rates. Second, wage earners may not understand the marginal incentives created by the EITC. Third, low income wage earners may not have the flexibility to adjust their labor supply (as employers may impose hours constraints) or may not be able to control their earnings accurately (as work opportunities may be highly stochastic). The latter explanation does not seem realistic because (a) in the long-run, individuals can adjust their earnings by changing jobs (the EITC was stable over the last 10 years in our data), (b) longitudinal tax data show that the year-to-year variability in earnings for low income earners is not large enough to smooth out bunching around the kink point entirely unless the behavioral labor supply elasticity is very small.\(^{18}\) This leaves two explanations: low intensive elasticity or lack of knowledge about the EITC.

Lack of knowledge about the structure of the EITC is indeed confirmed by surveys of low and moderate income families (see e.g., Olson and Davis 1994, Romich and Weisner 2002). Those studies show that most EITC recipients have heard about the EITC but only a very small minority knows about the EITC marginal incentives and the location of the kink points.\(^{19}\) Indeed, none of the EITC advertising materials created by the government, nonprofit organizations, or tax preparers and aiming at informing the public about the EITC, depicts the pyramid shape of the EITC, or the location of the kink points. Interestingly, Chetty and Saez (2009) show that providing simple but salient information about the EITC structure to EITC recipients leads to behavioral responses in reported wage earnings the following year. Therefore, we believe that, currently, there is lack of knowledge about the EITC structure among wage earners and that this lack of knowledge causes the intensive elasticity of earnings with respect to marginal incentives to be low. If knowledge were higher, the intensive elasticity

\(^{18}\)Saez (1999) develops models of limited job choices and stochastic earnings calibrated with the data to make this point formally.

\(^{19}\)For example, in the 42 families sampled by Romich and Weisner (2002), 90% had heard of the EITC, but only two families knew that they needed to earn a certain amount to maximize their credit and only one of those two families aimed at reporting self employment earnings to maximize the credit (p. 378).
would likely be higher as well.

Our second finding is that the self-employed display significant bunching evidence. Consistent with the standard model, the self-employed are likely to be more responsive to marginal incentives because they may have more flexibility to adjust their labor supply or can mis-report their income with less risk of being caught evading. In contrast to wage earners, the government does not receive third party reports about most of the income and costs items reported by the self-employed. As a result, tax evasion for self-employment income can only be detected with costly audits. Indeed, in the case of small informal business suppliers, the IRS estimates that the rate of income under-reporting is extremely high—over 80% for tax year 1992 (US Treasury, 1996, Table 3, p. 8). As shown by Feldstein (1999), such tax avoidance behavior can be easily be modelled using the standard two good utility framework introduced in Section 2 as long as the costs of evasion are convex with the level of evasion. However, our bunching evidence among the self-employed remains inconsistent with the standard model in two important ways.

First, bunching is found only at the first kink point and not at the second kink point (nor is there evidence of a gap in the earnings density at the third concave kink point). Second, even at the first kink point, bunching arises only when the EITC subsidy rate is over 15%: bunching evidence starts in 1991 when the EITC subsidy rate is above 16%, and becomes very large with the modern EITC with subsidy rates of 34% and 40%. We have also verified that no bunching develops with the EITC for filers with no children with a subsidy rate of 7.65%.

Importantly, self-employment income reported on individual tax returns also faces the Social Security and Medicare payroll tax at a rate of 15.3%. For the self-employed, the payroll tax is administered with the individual income tax return. Therefore, the first kink of the EITC is the point that maximizes the net transfer received from the government when the EITC subsidy rate is over 15.3% (and is therefore smaller than the full payroll tax rate on the self-employed at the margin). Many low income earners do have some informal self-employment income because they perform informal services for pay such as child care, cleaning,

---

20 In reality, the effective rate is slightly lower as the payroll tax applies to a base of 92.35% of self-employment income (to be equivalent to the sum of employer and employee payroll taxes in the case of wage earnings). However, the EITC is also based on 92.35% of self-employment income. Hence, the rate of 15.3% is the relevant number to compare to the nominal EITC subsidy rate.

21 The EITC first kink point remains the income level maximizing the net transfer received from the government even after the introduction of the refundable child tax credit in 2001.
landscaping, house or car maintenance, etc. This informal income cannot be monitored by the IRS and is therefore in general not reported on tax returns (which explains the extremely large 80% evasion rate for informal supplier business income mentioned above). However, with an EITC subsidy rate above the payroll tax rate, it is to the advantage of low income earners to report such informal self-employment income. As the IRS cannot monitor the amounts, it is also possible to over-report such informal self-employed income.\textsuperscript{22}

### 3.4 A Simple Model of Tax Reporting

The following simple model of behavior can account for all the facts we have uncovered in our empirical analysis. Each individual has formal earnings $w \geq 0$ (wages and salaries or formal self-employment income reported to the IRS on third party W2 or 1099 forms) and informal earnings $y \geq 0$ (self-employment income not reported on third party 1099 forms). Let us assume that both $w$ and $y$ do not respond to taxes along the intensive margin (responses along the extensive margin would not affect the analysis and are ignored) and are smoothly distributed in the population.

Individuals cannot misreport formal earnings $w$ because of third party reporting to the IRS. However, individuals can misreport $y$. Let us denote $\hat{y}$ the amount of informal earnings reported for tax purposes. Taxes and transfers are based on $w + \hat{y}$ so that net disposable income is $c = w + y - T(w + \hat{y})$.

The critical element to obtain bunching solely at the first kink point global maximum and not at the other kink points is to assume away convex preferences and instead use linear preferences with fixed costs.

Let us assume that there is an administrative fixed cost $q_A$ to report $\hat{y} > 0$ which represents record keeping, filing additional tax schedules, as well as determining the corresponding tax liability. This cost is independent of $\hat{y}$ and is paid as long as $\hat{y}$ is positive (as not reporting any informal earnings is administratively costless). We further impose the constraint that $\hat{y} \geq 0$ by assuming that $\hat{y} < 0$ would trigger an audit. As mentioned above, EITC bunching is not generated by those reporting negative self-employment income.

\textsuperscript{22}Interestingly, we find that the spike around the first kink point is entirely due to tax filers reporting positive self-employment income and not at all to tax filers reporting negative self-employment income, suggesting that tax filers in the phasing-out range do not avoid taxes by reporting exaggerated business losses. An explanation could be that net business losses are much more likely to trigger an IRS audit than business gains.
There is also a moral fixed cost $q_M$ of misreporting $y$ that is paid whenever $\hat{y} \neq y$. This latter cost can be a moral cost of cheating the government or can represent the risk of being audited and caught misreporting income by the IRS. Importantly, the fixed cost $q_M$ does not depend on the amount misreported which we denote by $y$.\footnote{If the IRS can demonstrate that self-employment income was misreported (which is actually difficult in the case of informal business income), then the tax filer has to pay the evaded tax. As fines are rarely imposed in the case of small amounts, there is little monetary cost to cheating. Therefore, the fixed cost represents the psychological cost of going through the process of being audited by the IRS. McCubbin (1999) reports that, although less than 20\% of EITC report self-employment income, 50\% of audited EITC returns which have income errors reported some self-employment income.} We assume for simplicity (and without affecting the analysis) that utility is quasi-linear in disposable income $c$. Therefore, an individual chooses $\hat{y}$ to maximize:

$$w + y - T(w + \hat{y}) - q_A \cdot 1(\hat{y} > 0) - q_M \cdot 1(\hat{y} \neq y).$$

Let us assume that $-T(z)$ is single peaked and that $z^*$ is the unique reported income which maximizes the government net transfer $-T(z)$. The US federal, state, and payroll tax system does generate such single peaked transfers. If the EITC subsidy rate is above the payroll tax rate, then $z^*$ is at the first kink point of the EITC and otherwise, $z^* = 0$. Let us assume further that the distribution of costs $(q_A, q_M)$ is smooth in the population. We can state the following formal proposition.

**Proposition 1** In our reporting model with non-convex preferences, we have

(a) The optimal report for self-reported income $\hat{y}$ can take only three values: (1) truthful reporting $\hat{y} = y$, (2) complete evasion $\hat{y} = 0$, or (3) maximizing the tax refund $\hat{y} = z^* - w$.

(b) If $z^* > 0$ (i.e., the EITC subsidy rate is larger than the payroll tax rate), then an atom of tax filers will bunch at the first kink point of the EITC $z^*$.

**Proof:** For (a), consider first the case where $z^* - w \geq 0$ and suppose that $\hat{y} > 0$ and $\hat{y} \neq y$, then $\hat{y}$ delivers at least as much utility as reporting $z^* - w$, hence $-T(w + \hat{y}) \geq -T(z^*)$. As $z^*$ uniquely maximizes $-T(z)$, it must be the case that $w + \hat{y} = z^*$. Hence if $z^* - w \geq 0$, we are necessarily in scenario (1), (2), or (3).

Second, consider the case $z^* - w < 0$ where the first kink point is not reachable with any $\hat{y} \geq 0$. Because $-T(z)$ is single peaked, $\hat{y} = 0$ maximizes $-T(w + \hat{y})$. Therefore, if $\hat{y} \neq y$, then $\hat{y} = 0$ is the optimal choice. So, we are necessarily in scenario (1) or (2).
For (b), from (7), the tax filer chooses scenario (1), (2), or (3) depending on which of the three expressions, (1) \( w + y - T(w + y) - q_A \cdot 1(y > 0) \), (2) \( w + y - T(w) - q_M \cdot 1(y \neq 0) \), (3) \( w + y - T(z^*) - q_A \cdot 1(z^* - w > 0) - q_M \cdot 1(y \neq z^* - w) \), is largest.

Assuming that \( z^* > 0 \), then all filers such that \( q_M < T(w + y) - T(z^*) \) and \( q_A < T(w) - T(z^*) \) will bunch at the kink. Because \( z^* \) is the single global maximum of \(-T(z)\), we have \( T(w + y) - T(z^*) > 0 \) and \( T(w) - T(z^*) > 0 \) for \( w \neq z^* \) and \( w + y \neq z^* \). Therefore, as \( q_M \) and \( q_A \) are smoothly distributed, there is a positive measure of tax filers bunching at the kink point \( z^* \). QED.

Three points are worth noting. First, if the EITC subsidy rate is smaller than the payroll tax rate, then \( z^* = 0 \). Tax filers are either truthful or do not report informal earnings at all and there is no bunching at the first kink of the EITC. This represents the standard case described in Tax Compliance studies where most informal self-employment earners do not report their self-employment income.

Second, when the EITC subsidy rate becomes larger than the payroll tax rate, then bunching develops at the first kink point of the EITC. Bunching tax filers are tax filers who previously did not report at all their self-employment income (for whom the gain of maximizing the net credit is larger than the administrative cost \( q_A \)) or tax filers who were previously truthful (for whom the gain of maximizing the net credit is larger than the moral cost \( q_M \)). Consistent with the evidence, there will be no bunching at the second kink point because that point does not maximize the net tax credit.

Third, the amount of bunching depends positively on the size of the net-tax credit \(-T(z^*)\). The increased bunching that we observed overtime on Figure 5 could be modelled as a learning process. Tax filers learn slowly overtime from others or from tax preparers that reporting \( z^* \) maximizes net tax transfers. Importantly, increasing the EITC at the margin generates deadweight burden in our model because tax filers who change their behavior because of the (marginal) EITC change generate a first order fiscal cost but experience a second order welfare gain. Therefore, as in the standard theory, the indirect fiscal costs due to behavioral reporting responses are deadweight burden. The size of the marginal deadweight burden is proportional to the size of the behavioral response. The relevant concept is the elasticity of bunching with respect to the net-transfer \(-T(z^*)\). This elasticity depends on the distribution of fixed costs.
\((q_A, q_M)\) as well as on the distribution of earnings \((w, y)\) in the population.

4 Federal Income Tax Empirical Results

4.1 Background on Federal Income Tax Computation

For federal income tax purposes, taxable income is defined as Adjusted Gross Income (AGI) less personal exemptions (a fixed amount per person in the tax unit) and deductions. Deductions can take the form of a standard deduction (a fixed amount depending on marital status: single, married, or head of household) or of itemized deductions whichever is larger. Itemized deductions include state and local income and property taxes, mortgage interest payments, charitable contributions, and other smaller items. Income tax is computed as a function of taxable income using a piece-wise linear schedule with increasing marginal tax rates.\(^{24}\) The size of the tax brackets depends on marital status. The relevant income measure to study bunching around the kinks of the regular federal income tax schedule is therefore taxable income.

Before the Tax Reform Act (TRA) of 1986, there was a large number of tax brackets (between 15 and 25 depending on years) and thus jumps in marginal tax rates from bracket to bracket were small (from 1 to 5 percentage points in general), except for the first bracket where tax liability begins. As shown on Table 3, Panel A, the first bracket had a tax rate between 14\% and 20\% depending on years. Moreover, before TRA 1986, the tax schedule was not indexed for inflation, and thus the real location of kinks changed substantially from year to year during the inflationary episodes of the 1970s (this phenomenon was called ‘bracket creep’). The exemption and standard deduction amounts were also adjusted periodically to mitigate ‘bracket creep’. Thus, we limit our study of bunching in the pre-TRA era primarily to years 1960 to 1969, when inflation was low and the tax schedule stable, and only to the vicinity of the first kink point.\(^{25}\) As described in Panel A of Table 1, the income tax structure has been remarkably stable from 1948 to 1963, with the exemption level per person fixed at $600 (in nominal dollars), and the standard deduction defined as 10\% of AGI (up to a maximum standard deduction limit of $1,000) and the first marginal tax rate equal to 20\%.

\(^{24}\)There are a number of exceptions to that rule, such as favorable treatment of realized capital gains or the alternative minimum tax.

\(^{25}\)An earlier version of the paper, (Saez, 1999), analyzes in detail years 1979 to 1986 and finds no evidence of bunching or clustering, except around the first kink point.
In 1964, a more advantageous standard deduction equal to $200 plus $100 times the number of exemptions was introduced. Finally, due to inflationary pressures, the modern standard deduction was introduced in 1970 and the exemption levels increased.

After the Tax Reform Act of 1986, the number of tax brackets was drastically reduced and exemptions, standard deductions, and tax brackets have been indexed to the Consumer Price Index. Table (Panel B) describes the tax schedule for years 1988 to 2008 (expressed in dollars of 2008). The tax structure has changed relatively little from 1988 to 2001, and includes two major kinks: the first kink where the marginal tax rate jumps from 0 to 15%, and the second kink with a jump from 15 to 28%. Note that two extra tax brackets have been introduced in 1993, creating jumps from 31 to 36% and 36% to 39.6% for high income earners. In 2002, a bottom bracket with a lower rate of 10% was introduced so that the jump in marginal tax rate at the first kink point is from 0% to 10%. Furthermore, the upper rates has also been reduced from 2001 to 2003.

Non-refundable tax credits are items that reduce positive tax liability.\(^{26}\) As long as the net-of-credits tax liability remains positive, such non-refundable tax credits have no impact on the marginal tax rate and hence the location of the kink point. However, if the non-refundable tax credits are large enough to reduce the tax to zero, then they change the marginal tax rate from the statutory rate down to zero (as an extra dollar of income would no longer translate into a net-tax increase). Therefore, the first kink point of the tax schedule starts at zero taxable income only for tax filers with no tax credits. If the tax filer has non-refundable credits equal to \(d\), the first kink point is at taxable income \(z = d/\tau_1\) where \(\tau_1\) is marginal tax rate in the first tax bracket. This fact is important as the Child Tax Credit, introduced in 1998, effectively shifts the first kink away from zero taxable income for most low income tax filers with children, a point we explore below.

### 4.2 Bunching Evidence around the First Kink Point from 1960-1972

Figure 6 displays the density distributions of taxable income (expressed in 2008 dollars) aggregating years 1960 to 1969\(^{27}\) for married joint filers (Panel A), and singles and heads of household (Panel B). The marginal tax rate schedules are also displayed (for year 1960) in

\(^{26}\)Non-refundable credits cannot reduce tax liability below zero. In contrast, refundable tax credits (such as the EITC) are paid even if the tax liability falls down to zero.

\(^{27}\)Years 1961, 1963, and 1965 are not included because no micro file was created for these years.
dashed line. In all years, the first kink point is at zero as depicted by the vertical line. Both panels display striking visual evidence of bunching at the first kink point of the tax schedule. In both cases, the density peaks just before the first kink point, providing compelling evidence that the change in marginal tax rates around the first kink point produces a behavioral response of reported taxable income. A potential objection is that individuals may not systematically file tax returns in the negative range of taxable income as no tax liability is due. Figure 6, however, shows that there is no missing density just below the kink at the density is actually higher just below the kink. Indeed, in practice, withholding on wage income starts below the zero taxable income threshold so that most filers with low wage income and negative taxable income file to obtain a tax refund.

Figure 7 casts further light on the mechanism behind the bunching uncovered on Figure 6 by plotting the kernel density of taxable income (as in Figure 6) along with the density of taxable income computed using the standard deduction, i.e., defined as adjusted gross income minus personal exemptions and minus the standard deduction (even for itemizers). The graphs show that bunching is much more pronounced for actual taxable income than for taxable income computed with the standard deduction, especially in the case of married filers (Panel A). This shows that the bunching phenomenon is in large part due to the response of itemized deductions. We expect indeed itemizers to be able to bunch exactly at the spike because some of the itemized deductions such as charitable contributions might be manipulated much more easily than earnings. For example, some taxpayers who itemize deductions might bunch exactly at the kink because they may stop reporting deductions once they have reached the threshold of no tax liability. Note however, that even taxable income computed with the standard deduction displays some bunching around the first kink point suggesting that part of the response is an adjusted gross income response.

Figure 8 casts light on the dynamics of bunching by showing taxable income densities for three periods: 1960-1963, 1964-1969, and 1970-1972. As discussed above, from 1954 to 1963, the tax system around the first kink point was totally stable in nominal terms and inflation was low. In 1964-65, the standard deduction was expanded and the first tax rate lowered from 20 to 14 percent. Finally, in 1970-72, because of high inflation and the concern of ‘bracket creep’, both the personal exemptions and standard deductions were further expanded from year to year. Figure 8 shows that tax filers are not able to adapt immediately to the changes
in the tax system and that bunching is less pronounced in the last two periods and especially in 1970-72 when the tax system changes every year. This is consistent with our previous EITC evidence showing that it takes time for filers to learn and respond to the tax system.

4.3 Bunching Evidence from 1988-2004

Figure 9 displays the histograms of the density distributions of taxable income (expressed in 2008 dollars) aggregating years 1988 to 2002\(^{28}\) for married joint filers (Panel A), and singles (excluding heads) (Panel B).\(^{29}\) The marginal tax rates are depicted in dashed line, and the first and second kink points (which are exactly aligned for all years) are depicted with vertical lines. Two points are worth noting. First, both panels display compelling visual evidence of bunching at the first kink point although perhaps not as strong as in the 1960-1969 period examined earlier. There is a noticeable spike at the first kink, and the density distribution appears stretched at this point. Second, there is absolutely no evidence of bunching at the second kink point where marginal tax rate jump from 15 to 28% even though this kink is large and has remained stable throughout the period 1988-2002. Restricting the sample to filers with self-employment income or realized capital gains does not generate bunching evidence. Further exploration around the upper kink points does not uncover any bunching evidence either. We omit the graphical evidence to save space and simply present some elasticity estimates below.

Figure 10 provides additional evidence on bunching around the first kink point. Panel A displays the kernel density for taxable income and taxable income computed using the standard deduction (as in Figure 7). The sample includes all filers married, singles, and heads. Consistent with the period 1960-1969, bunching is much less sharp for taxable income computed using the standard deduction but does not disappear entirely showing that part of the response is an income response and part of the response goes through itemized deductions.

Panel B shows further evidence that the bunching at zero taxable income is indeed created by the jump in marginal tax rate by exploiting the introduction and development of the child tax credit in 1998. As mentioned above, with non-refundable credits, the first kink in the

\(^{28}\)We do not include years 2003 and 2004 as the location of the 2nd kink point changed for joint filers (see Table 3).

\(^{29}\)We have removed from the sample taxpayers who can be claimed as dependents by other taxpayers (these are mostly children with income) as their standard deduction is subject to special rules. These rules tend to make their taxable income artificially and mechanically close to zero even in the absence of any behavioral response.
budget set is actually not at zero taxable income but at \( z = \frac{d}{\tau_1} \) where \( \tau_1 \) is marginal tax rate in the first tax bracket and \( d \) is the amount of potential tax credits. Virtually all filers with low taxable income and children qualify for the (non-refundable) child tax credit introduced in 1998 (as the refundable portion is not large enough to eliminate tax liability entirely in most cases, see footnotes in Table 3). Therefore, after 1998, tax filers with children do not face a kink at zero taxable income and hence should not bunch at zero. Figure 10, Panel B, displays the density for tax filers with children and tax filers without children for the period 1998-2004 and shows indeed that bunching disappears for tax filers with children during the period.

4.4 Elasticity Estimates

Table 4 provides elasticity estimates based on the graphs displayed earlier and confirms our visual evidence. Four points are worth noting. First, Panel A shows that the elasticity estimates are consistently positive and significant and around 0.2 around the first kink point both for the 1960-1969 period and the recent 1988-2002 period. Second, Panel B shows that estimates are somewhat sensitive to the choice of the bandwidth \( \delta \) in the estimation. As in the case of our EITC based estimates, large bandwidth generate larger elasticities as the excess bunching will be larger. Note that even with lower bandwidth, the estimates remain significant. Third, Panel C shows that estimates are largest for the 1960-1963 period and are reduced significantly by 1970-1972 especially for single filers confirming our finding that it takes time for tax filers to adapt to a new tax schedule. Fourth, Panel D shows that estimated are zero and precisely estimated around the higher kink points in the recent period, even when the sample is restricted to those with positive self-employment income. Our bunching evidence for higher kink points is not consistent with the standard model of labor supply which underpins most recent studies on the elasticity of taxable income with respect to net-of-tax rate (see Saez, Slemrod, and Giertz, 2009 for a recent survey) if taxable income elasticities are substantial.

5 Conclusion

Our analysis has found substantial evidence of bunching around the first kink point of the EITC but concentrated among those reporting self-employment income. For the federal income tax, we have found evidence of bunching only at the first kink point where tax liability starts with no evidence of bunching for higher kink points. We have also developed an econometric
method which uses bunching evidence to estimate the intensive elasticity of reported income with respect to (one minus) the marginal tax rate in the standard micro-economic model.

However, a number of our empirical findings suggest that the standard intensive model cannot fully account for the facts. In the case of the EITC, we have shown that our empirical findings can be much better explained by a fixed cost model of misreporting informal self-employment income. In contrast to the standard model, such a model can explain why we observe bunching solely for the self-employed and solely around the first EITC kink point (and not around the other EITC kink points) and only when the EITC subsidy rate is larger than the payroll social security tax. Furthermore, the evidence of growing bunching overtime suggests that information on how to game the EITC with self-employment income diffuses slowly in the population.

The contrasting evidence of bunching around the first kink point of the federal income tax with no bunching evidence at all around higher kink points also implies that the standard model misses a key element. The most realistic explanation seems to be the difficulty for tax filers to understand the exact details of a complex tax system. The first kink point where tax liability starts is likely to be more salient than other kink points. Furthermore, the simpler and more stable tax system of the 1960s is likely to have made the first kink point more salient. There is a growing literature in behavioral economics that has shown that such framing effects appear in a wide set of circumstances. In the present context, the fact that framing effects matter has intriguing consequences.

First, the results show that the effects of taxes and transfers depend critically on salience characteristics. Therefore, this implies that the central elasticity of income with respect to marginal tax rates is not a single structural parameter but depends upon the salience characteristics of the particular program. Therefore, such salience factors should be included as a key explanatory variable in empirical estimation of behavioral responses.\footnote{For example, the results of this paper suggest that empirical strategies using local variation in marginal tax rates (such as Gruber and Saez 2002 or Saez 2003) due to the bracket structure of the income tax might under-estimate the effects of large and salient tax reforms.} Similarly, the long-run effects of policies could be very different from the effects of short-run changes in policy parameters since information about small changes may diffuse slowly. This aspect is developed specifically in Chetty et al. (2009) who show that large changes generate more elastic responses than small changes. Second, from a modelling perspective, as informational considerations are
a central aspect of the size of the behavioral response, it is important to develop models of how individuals learn about a budget set and its consequences for the optimal design of tax and transfer policies.\textsuperscript{31}

The results of this paper suggest other directions for future research. First, the elasticity estimation framework could be applied to other contexts where nonlinear budget sets create convex kink points and where individuals are likely to be aware of those kinks. Examples include (1) the Social Security earnings test where previous work (Burtless and Moffitt 1984, Friedberg, 2000) has found evidence of bunching consistent with the standard model, (2) 401(k) pension contributions where employers often provide a match up only up to some level of contributions and where numerous studies have documented evidence of bunching of contributions where the cap ends (see e.g., Choi et al. 2002), (3) retirement decisions as public and private defined benefits retirement systems often introduce kinks in the lifetime budget constraint,\textsuperscript{32} (4) household consumption of utilities (such as telephone, water, gas, and electricity) where pricing is often piecewise linear,\textsuperscript{33} (5) tax systems in other countries which sometimes offer larger and more transparent kink points than the US system. Chetty et al. (2009) have just proposed such an analysis for Denmark. In all of those cases, it would be particularly valuable to analyze whether providing information about the nonlinearities could affect behavior.\textsuperscript{34}

\textsuperscript{31}Recent studies in behavioral public economics have begun to characterize optimal policies when agents do not have full information and optimize imperfectly relative to government policies. See Liebman and Zeckhauser (2004), Chetty, Kroft, and Looney (2008).

\textsuperscript{32}As mentioned in introduction, Brown (2007) proposed a bunching based elasticity estimation using reforms in the California Teachers retirement program.

\textsuperscript{33}Borenstein (2008) analyzes the case of nonlinear electricity pricing in California and finds no evidence of bunching.

\textsuperscript{34}Chetty and Saez (2009) show that information about the EITC does increase the amount of bunching around the first kink point of the EITC.

Before tax income \( z \)

Density distribution

Pre-reform incomes between \( z^* \) and \( z^* + dz^* \) bunch at \( z^* \) after reform

After reform density

Before reform density

Figure 1. Bunching Theory

Panel A displays the effect on earnings choices of introducing a (small) kink at the budget set by increasing the tax rate \( t \) by \( dt \) above income level \( z^* \). Individual L who chooses \( z^* \) before the reform stays at \( z^* \) after the reform. Individual H chooses \( z^* \) after the reform and was choosing \( z^* + dz^* \) before the reform.

Panel B depicts the effects of introducing the kink on the earnings density distribution. The pre-reform density is smooth around \( z^* \). After the reform, all individuals with income between \( z^* \) and \( z^* + dz^* \) before the reform, bunch at \( z^* \), creating a spike in the density distribution. The density above \( z^* + dz^* \) shifts to \( z^* \) (so that the resulting density and is no longer smooth at \( z^* \)).
Figure 2. Estimating Excess Bunching using Empirical Densities

This figure illustrates the excess bunching estimation using empirical densities. We assume that, under a constant linear tax with rate $t_0$, the density of income $h_0(z)$ is smooth. A higher tax rate $t_1$ is introduced above $z^*$, creating a convex kink at $z^*$. The reform will induce tax filers to cluster at $z^*$, creating a spike in the post-reform density distribution $h(z)$. As illustrated on the figure, bunching might not be perfectly concentrated at $z^*$ because of inability of tax filers to control or forecast their incomes perfectly or imperfect information about the exact kink location. For estimation purposes, we define three bands of income around the kink point $z^*$ using the bandwidth parameter $\delta$. The lower band is the segment $(z^* - \delta, z^* - 2\delta)$, it has average density $h(z^*)$, and hence includes $H^* = \delta h(z^*)$, tax filers (blue dashed left area). The upper band is the segment $(z^* + \delta, z^* + 2\delta)$, it has average density $h(z^*)$, and hence includes $H^* = \delta h(z^*)$, tax filers (blue dashed right area). The middle band is the segment $(z^* - 2\delta, z^* + 2\delta)$ and includes $H^* = \delta$ tax filers. Excess bunching is defined as $B = H^* - (H^* - + H^* +) = excess\ bunching$. If clustering of tax filers around $z^*$ is tight, excess bunching will be estimated without bias with a small $\delta$. If clustering is not tight around $z^*$, a small $\delta$ will underestimate the amount of excess bunching (as the lower and upper bands will include tax filers clustering around $z^*$). However, a large $\delta$ will lead to overestimate (underestimate) excess bunching if the before reform density $h_0(z)$ is convex (concave) around $z^*$. 
Figure 3. Earnings Density Distributions and the EITC
The figure displays the histogram of earnings (by $500 bins) for tax filers with one dependent child (Panel A) and tax filers with two or more dependent children. The histogram includes all years 1995-2004 and inflates earnings to 2008 dollars using the IRS inflation parameters (so that the EITC kinks are aligned for all years). Earnings are defined as wages and salaries plus self-employment income (net of one-half of the self-employed payroll tax). The EITC schedule is depicted in dashed line and the three kinks are depicted with vertical lines. Panel A is based on 57,692 observations (representing 116 million tax returns) and Panel B on 67,038 observations (representing 115 million returns).
Figure 4. Earnings Density and the EITC: Wage Earners vs. Self-Employed
The figure displays the kernel density of earnings for wage earners (those with no self-employment earnings) and for the self-employed (those with non-zero self-employment earnings). Panel A reports the density for tax filers with one dependent child and Panel B for tax filers with two or more dependent children. The charts include all years 1995-2004. The bandwidth is $400 in all estimations. The fraction self-employed in 16.1% and 20.5% in the population depicted on Panels A and B (in the data sample, the unweighted fraction self-employed is 32% and 40%). We display in dotted vertical lines around the first kink point the 3 bands used for the elasticity estimation with $\delta = 1,500$. 

**A. One Child**

**B. Two or More Children**
Figure 5. Earnings Density and the EITC: Bunching Increases over Time
The figure displays the kernel density of earnings for the self-employed only for 1995-1999 (dotted line) and 2000-2004 (solid line). Panel A reports the density for tax filers with one dependent child and Panel B for tax filers with two or more dependent children. The bandwidth is $600 in all estimations. The data sample sizes underlying those density estimates are 8,436 (1995-9, one child), 9,883 (1995-9, 2+ children), 12,256 (2000-4, one child), 14,308 (2000-4, 2+ children). The corresponding full population sizes are 8.8, 9.9, 11.2, 12.4 million respectively (when adding all years).
Figure 6. Taxable Income Density, 1960-1969: Bunching around First Kink
The figure displays the histogram of taxable income for married joint tax filers (Panel A) and single tax filers defined as all non married joint filers (Panel B). The data include years 1960, 1962, 1964, 1966-1969 (no data are available for 1961, 1963, and 1965). Histograms are based on bins $800 wide and are computed using population weights (unweighted sample sizes for Panel A and B histograms are 185,161 and 82,859 respectively). Taxable income is defined as Adjusted Gross Income minus personal exemptions minus the maximum of the standard or itemized deductions, and is expressed in 2008 dollars. The marginal tax rate schedule is displayed for 1960 in dashed line. In all years, the first kink point is at zero taxable income displayed by the vertical line on the graph (other kink points move from year to year as tax brackets are not adjusted for inflation from 1960 to 1969). The first bracket marginal tax rate is 20% from 1960-1963, 16% in 1964, and 14% in 1965-1969 (see Table 3, Panel A).
Figure 7. Taxable Income Density, 1960-1969: Itemizing Effects on Bunching

The figure displays the kernel density of income (in 2008 dollars) for married joint tax filers (Panel A) and single tax filers (Panel B). In each panel, the solid line is the density of actual taxable income defined as in Figure 6 as Adjusted Gross Income minus personal exemptions minus the maximum of the standard or itemized deductions, while the dotted line is the density of taxable income computed solely with the standard deduction, i.e., defined as Adjusted Gross Income minus personal exemptions minus the standard deductions. Both definitions coincide for non-itemizers and differ for itemizers. This comparison allows to evaluate the contribution of itemization to bunching. The data include years 1960, 1962, 1964, 1966-1969. Densities are computed using population weights. Sample sizes are the same as in Figure 6. Bandwidth is $500 in kernel density estimation.
Figure 8. Taxable Income Density, 1960-1972: Dynamics of Bunching

The figure displays the kernel density of taxable income (in 2008 dollars) for married joint tax filers (Panel A) and single tax filers (Panel B) for 3 periods 1960-1963 (solid line), 1964-1969 (dashed line), and 1970-1972 (dotted line). Densities are computed using population weights. As shown in Table 3, the definition of taxable income was stable (in nominal terms) from 1948 to 1963 and was changed in 1964 and in 1970. The graphs show that bunching decreased sharply after the reforms showing that it takes time for tax filers to bunch, especially for single filers where bunching is primarily due to income responses instead of itemized deduction responses for married filers. Sample sizes for ’60-’63, ’64-’69, ’70-’72 are 76,515, 108,646, 69,365 in Panel A and 34,636, 48,223, 21,775 in Panel B. The bandwidth is $500 in the kernel estimation.
Figure 9. Taxable Income Density, 1988-2002
The figure displays the histogram of taxable income for married joint tax filers (Panel A) and single tax filers (excluding heads of households) (Panel B). The data include years 1988 to 2002. Histograms are computed using population weights (unweighted sample sizes for Panel A and B histograms are 368,173 and 239,225 respectively representing population sizes of 594 million and 587 million tax filers). Taxable income is defined as Adjusted Gross Income minus personal exemptions minus the maximum of the standard or itemized deductions, and is expressed in 2008 dollars. The marginal tax rate schedule is displayed in dashed line. Both the first and second kink points are displayed by the vertical lines on the graph and are exactly aligned in all years as the tax system is indexed for inflation (see Table 3).
Figure 10. Taxable Income Densities: Itemizing and Child Tax Credit Effects

The figure displays the kernel density of income (in 2008 dollars). In Panel A, the solid line is the density of actual taxable income while the dashed line is the density of taxable income computed solely with the standard deduction (see Figure 7). The data include years 1988 to 2002 and all filers. The sample size is 516,859 representing 1,110 million tax filers. The bandwidth is $400 in the kernel estimation.

In Panel B, the data include years 1998 to 2004, the solid line if for filers with dependent children while the dashed line is for tax filers with no dependent children. From 1998 to 2004, the child tax credit shifts the first kink point to a positive taxable income threshold (which varies across tax filers). As a result, bunching is less pronounced at the zero taxable income threshold for tax filers with children. Sample size are 93797 (children) and 176411 (no children) representing 194 million and 357 million filers. Bandwidth is $500.

---

[1] In 1991-1993, EITC subsidy and tax rates depend on number of children (but brackets do not). In 1991: phase-in rates are 16.7% (1 child) and 17.3% (2+ children). Phase-out rates are 11.9% and 12.4%. In 1992: phase-in rates are 17.6% (1 child) and 18.4% (2+ children). Phase-out rates are 12.6% and 13.1%. In 1993: phase-in rates are 18.5% (1 child) and 19.5% (2+ children). Phase-out rates are 13.2% and 13.9%.

[2] In 2002-2004, EITC plateau for married filers is extended by $1,000 ($2,000 in 2005-2007, and $3,000 in 2008).

In 1995, phase-in and phase-out rates were -36% and 20.2% for EITC beneficiaries with two or more children.

Notes: This table presents estimates of the elasticity of earnings with respect to the net-of-tax rate based on bunching evidence around EITC kink points as described in Section 2.2 to the text. Standard errors are computed using the delta method. Bootstrap standard errors are also reported for the first row of estimates. The self-employed only sample (cols. (3) and (4)) is defined as EITC recipients with non-zero self-employment income. The wage earners only sample (cols. (5) and (6)) is defined as EITC recipients with zero self-employment income. In all cases, earnings are adjusted to 2008 dollars using the IRS inflation indexation (so that kinks are aligned across years). From 1995-2004, the EITC is large (phasing-in rates of 34% and 40% and maximum benefit of $2,917 and $4,824 in 2008 for tax filers with 1 child and 2+ children). From 1988 to 1993, the EITC was smaller and did not distinguish vary between 1 child vs. 2+ children beneficiaries. As a result, we pool together the 1 child and 2+ children groups for those years). See Table 1 for complete EITC structure details.

[1] Since 1987, exemptions and standard deduction are sharply reduced for tax filers who can be claimed as dependents (typically minor children, and students supported by their parents).

[2] The Child Tax Credit introduced in 1998 shifts the first tax bracket for tax filers with qualifying children as tax liability does not start until the child tax credit is fully phased-in. Even when the child tax credit becomes partly refundable in 2001, the first tax bracket is shifted as the child tax credit is not fully phased-in when the nominal first bracket starts.

[3] For 2001, rates were reduced to 15%, 27.5%, 30.5%, 35.5%, 39.1%.

For 2002, rates were 10%, 15%, 27%, 30%, 35%, 38.6%.

</tbody>
</table>

Notes: This table presents estimates of the elasticity of taxable income with respect to the net-of-tax rate based on bunching evidence around kink points as described in Section 2.2 to the text. All standard errors are computed using the delta method. In the case of the first kink point at zero taxable income, we define base income $z^*$ as average Adjusted Gross Income for tax filers with taxable income in $(-\delta,\delta)$ (as the elasticity is not defined at $z^*=0$). Column (1) includes all filers, column (2) includes only married filing jointly, while column (3) includes only single filers (defined as not filing jointly). In Panel D, single filers exclude heads of household (as the schedule for heads is not the same as for singles). In all cases, income and deductions are adjusted to 2008 dollars using the IRS inflation indexation (so that kinks are aligned across years). Complete details on tax rates and brackets are provided in Table 3.
